Abstract

A morphological and seismic-stratigraphic analysis of the Gulf of Cadiz area near the Strait of Gibraltar is presented in this work, focused on the sedimentary evolution of the upper and proximal middle-continental slope since the Mid-Pleistocene. Based on the analysis of seismic reflection profiles and swath bathymetry data, this work analyses the close influence of the activity of buried and outcropping diapiric ridges and late Quaternary sea-level changes on the evolution of contouritic features related to the Mediterranean Outflow Water (MOW) and Eastern North Atlantic Central Water (ENACW), gravitational features and fluid-escape structures. The stratigraphic architecture reveals that, under active diapiric deformation, the upper slope plastered drift grew during low sea-level stages, when sediment supply was high and the ENACW swept the upper slope, contrasting with the present-day highstand situation dominated by northwest-trending MOW flow. The south-estward ENACW flow forced asymmetry and lateral migration of gullies incised in the plastered drift. Two evolutionary stages have been established: 1) After the Mid Pleistocene, activity of diapirs with a NE trend determined the location of the deepest depressions which were infilled by plastered contouritic drifts; 2) Between Late Quaternary and present, a drastic change of buried diapirs growth pattern and orientation to a NW trend enhanced slope-derived gravitational processes affecting the bottom current dynamics. Adjustments to tectonic changes led to a phase of plastered drift growth on the upper slope during which depocenters varied their distribution and orientation. In a long-term the structural control on sedimentation shows a northwestward displacement of deformation, resulting in an overall extension of the contourite depositional system to the NW. In a short-term, sea-level changes favoured drift deposition, gullies incision and the strengthening of water masses. This work evidences the importance of tectonic deformation in sedimentation at recent time scales, and the two-directional interplay between recent tectonic activity and bottom current dynamics.

Keywords: Tectonics; Sea-level; Diapirs; Contourites; Gullies; Seismic stratigraphy; Continental slope; Gulf of Cadiz.

1. Introduction

Sedimentary processes in siliciclastic continental margins are controlled by the interactions of regional basin tectonics, sea-level fluctuations and sediment supply (Haq et al., 1987; Richards et al., 1998). In fact, tectonism may in the long term control climate and sea-level (Mack, 1978). Under this ultimate control, numerous sedimentary processes interplay in shaping continental margins (Nelson and Maldonado, 1988; Viana, 2009; Shanmugan, 2012). A growing body of evidence indicates that interactions between downslope gravitational processes and along-slope oceanograpic processes are ubiquitous in numerous deep-water settings (Howe, 1996; Gong et al., 2013; Fonnesu et al., 2020) and that they are of high importance in terms of hydrocarbon potential (Rodríguez and Hodgson, 2019). The interactions between turbidity flows and contour currents may be coeval (Mulder et al., 2008; Ercilla et al., 2019; de Castro et al., 2020), forming hybrid (or mixed) depositional systems which are represented in the stratigraphic record as unidirectionally migrating turbiditic channels (Gong et al., 2013, 2018; Li et al., 2013), asymmetric turbiditic channels, laterally migrating levees (Carter and Carter, 1988; Michels et al., 2002; Kuvaas et al., 2004; Sansom, 2018; Serra et al., 2020) that may eventually evolve into mixed contourite drifts (Rebesco et al., 2002), and laterally elongated fans (Fonnesu et al., 2020). Regional conditions may also favour the co-existence of turbiditic fans and contouritic drifts (Locker and Laine, 1992; Faugères et al., 1999; Michels et al., 2002; Ercilla et al., 2016; Juan et al., 2020). Another type of interaction is represented by turbidity systems reworked or even eroded by subsequent bottom current intensification (Locker and Laine, 1992; Mulder et al., 2009; Miramontes et al., 2019). In the opposite case, pre-existing contourite drifts may be dismantled by mass movements that evolve distally into turbiditic deposits (e.g., Martorelli et al., 2016; Teixeira et al., 2019). Finally, turbidites (or more generally, the products of mass flows) may alternate along time with contourites in the long term, where turbiditic products are progressively substituted by contourite drifts (Locker and Laine, 1992; Rasmussen et al., 2003), or driven by glacial-interglacial sea-level cyclicity, leading to high-frequency turbiditic-contouritic sequences (Mulder et al., 2009).

The Gulf of Cadiz hosts an extensive contourite depositional system, particularly documented along the Iberian margin, where the action of bottom currents over a complex, irregular seafloor topography has generated different morpho-sedimentary erosive and depositional sectors (Hernández-Molina et al., 2003, 2006; Llave et al., 2007a,b). Interactions between a number of gravity-driven and bottom current-related processes are common in the Gulf of Cadiz, such as: the development of gravitational erosive valleys that were later reoccupied by MOW filaments in the middle slope (Hanquiez et al.,

2010); long-term to short-term alternations between downslope mass wasting/turbidite systems and along-slope contourite systems (Brackenridge et al., 2013; Alonso et al., 2016; García et al., 2016; de Castro et al., 2020); deviation of the main MOW flow by submarine canyons and differential development of contourite drifts (Mulder et al., 2006; Marchès et al., 2007) and high-frequency turbidite-contourite variability in a slope terrace located between two submarine canyons (Marchès et al., 2010) south of Portugal.

In the Gulf of Cadiz continental slope close to the Strait of Gibraltar, interactions between contouritic and gravity-driven processes have not been fully appreciated. However, this area is ideal for studying such kind of interactions, due to the occurrence of several outcropping and buried diapiric bodies and ridges (Fernández-Puga et al., 2007), and their associated tectonic deformation (León et al., 2010). The obstacle effect caused by the diapiric structures may influence bottom currents, generating a suite of contourite depositional and erosional morphologies such as contourite channels and sediment drifts (Palomino et al., 2016; Schattner et al., 2018). In addition, oversteepening due to halokinetic processes and their associated overburden and faulting may favour the occurrence of slope instabilities and associated mass movements (Cashman and Popenoe, 1985; Tripsanas et al., 2003, 2004; Akinci and Sawyer, 2016; Maselli and Kneller, 2018).

The interactions between the MOW and the middle slope erosive and depositional features have been extensively studied and increased effort is invested in investigating the present-day influence of the oceanographic dynamics with sedimentary processes at the seafloor (Lozano et al., 2020). However glacio-eustatic cyclicity has been demonstrated to induce important changes in the spatial distribution of water masses along glacial cycles (Llave et al., 2001, 2006, 2007a,b, Toucanne et al., 2007; Marchès et al., 2010; Roque et al., 2012), suggesting that present-day morphology may result from oceanographic patterns that were significantly different from the current ones. Considering the existing knowledge gaps in understanding the evolution of this part of the margin, this study aims to understand how the interactions between tectonic, sedimentary and oceanographic processes have controlled the evolution of the continental slope in the vicinity of the Strait of Gibraltar. For this purpose, the study area extends from the upper slope to the proximal middle slope of the northern Gulf of Cadiz to a maximum water depth of about 600 m (36º10'-36º40'N, 6º30'-7º'W). In particular, this work aims at investigating the interactions between the diapiric structures and their associated tectonic deformation and the climatically controlled gravitational and contouritic processes since the middle Pleistocene.

2. Geological and oceanographic framework

2.1. Geological setting

The Gulf of Cadiz is located at the Atlantic side of the Strait of Gibraltar, limited to the north by the SW Iberian Peninsula and to the south by NW Africa (Fig. 1a). The present-day geological setting is the result of a complex tectonic history, after the opening of the Neo-Tethys and Central Atlantic in the Triassic (Terrinha et al., 2002; Medialdea et al., 2009), and a series of tectonic phases related to the movements along the African-Eurasian plate boundary (Rosenbaum et al., 2002). Half-graben and horst structures produced by Mesozoic extension were reactivated as dextral strike slip faults during Cenozoic compressional events (Lopes et al., 2006). During the Burdigalian-Middle Tortonian, the westward drift of the Alboran Crustal Domain generated the Betic-Rifean thrust belt during a compressive phase that reactivated NNW-SSE to NW-SE structures (Rosenbaum et al., 2002; Platt et al., 2003, 2013). As a result, the Allochthonous Unit of the Gulf of Cadiz (AUGC) was emplaced during the Late Tortonian (Torelli et al., 1997; Maldonado et al., 1999; Somoza et al., 1999; Medialdea et al., 2004, 2009; Gütscher et al., 2009, 2012) and was reactivated in the Late Miocene to Present due to NW compression. Salt diapirism rooted in Triassic evaporites and Miocene clay and marl diapirism related to the AUGC (Medialdea et al., 2009) have produced widespread NE-SW-oriented diapiric ridges (Cadiz, Guadalquiver and Doñana diapiric ridges, Fig. 1) that have been reactivated during the Pliocene–Quaternary as the result of adjustments in the allochtonous unit under a dominant NW-SE compressive regime (García et al., 2009; Fernández-Puga et al., 2010; Hernandez-Molina et al., 2016). Major structures in the Gulf of Cadiz (thrust faults, strike-slip faults, extensional faults and diapirs) favour the upward fluid escape that originate minor features as mud volcanoes and pockmarks (Casas et al., 2003; Somoza et al., 2003; Fernández-Puga et al., 2007).

2.2. Oceanographic setting

The present-day oceanographic setting of the Gulf of Cadiz is dominated by the water exchange between the Mediterranean Sea and the Atlantic Ocean, through the Strait of Gibraltar (Figs. 1a and 2). At the western side of the strait, the water column along the Gulf of Cadiz continental margin is occupied by distinct water masses. The inner shelf waters reach depths down to 60 m, impinging directly on the continental shelf and are subject to coastal and atmospheric influence (Bellanco and Sánchez-Leal., 2016; Sánchez-Leal et al., 2017). The low-salinity Eastern North Atlantic Central Water (ENACW) circulates with the same direction but at depths of 100-250 m, affecting the outer continental shelf and the shallower upper slope. Below, the Mediterranean Outflow Water (MOW) circulates towards the NW (Fig. 2b; Sánchez-Leal et al., 2017) sweeping most of the upper slope and the middle slope. The MOW, after exiting the Strait of Gibraltar at depths deeper than 150-200 m veers towards the NW, where it is affected by the interaction with the rough topography (Fig. 2a; Sánchez-Leal et al., 2017). Its upper boundary deepens as it flows north-westwards along the Gulf of Cadiz continental margin and it is split into two preferential pathways forming the Mediterranean

Upper Core (MU), that flows along the base of the upper slope, and the Mediterranean Lower Core (ML), flowing along the middle slope (Fig. 1a; Madelain, 1970; Zenk, 1975; Grundlingh, 1981; Borenäs et al., 2002; Serra et al., 2005, 2010; Sánchez-Leal et al., 2017). The modified Antarctic Intermediate Water (AAIW) also flows towards the NW, down to depths of 600-625 m, and confines the MOW and the ENACW against the continental slope (Louarn and Morin, 2011; Hernandez-Molina et al., 2014; Roque et al., 2019). Finally, the North Atlantic Deep Water (NADW) flows below the MOW towards the E-SE at water depths >1500 m (Zenk, 1975; Thorpe, 1976; Gardner and Kidd, 1983; Ochoa and Bray, 1991; Baringer and Price, 1999; Serra et al., 2005).

The oceanographic pattern in the Gulf of Cadiz is highly dynamic and exhibits drastic seasonal changes. During the month of March,cooler and less saline waters (temperature of 14.6ºC and practical salinity of 36.26) occupy the inner shelf due to the erosion of the seasonal thermocline and the increase in river water supply and denser MOW (colder and more saline) invades the upper slope, displacing the ENACW towards the shelf. In November conditions, the water stratification is intensified and the ENACW broadens and stretches eastwards (Bellanco and Sánchez-Leal, 2016). In addition, a displacement of the MOW toward the upper continental slope is further favored by the increased presence of AAIW and a reduction of the ENACW (Roque et al., 2019).

2.3. The Gulf of Cadiz Contourite Depositional System

The Gulf of Cadiz hosts a huge contourite depositional system (CDS), created by the MOW as it exits the Strait of Gibraltar into the Atlantic Ocean. This system has been extensively studied in the last decades (Gonthier et al., 1984; Nelson et al., 1993, 1999; Maldonado et al., 1999; Llave et al., 2001, 2007; Hernández-Molina et al., 2003, 2016; Roque et al., 2012), mostly focusing on the erosional and depositional features in the middle slope (Fig. 1a; Hernández-Molina et al., 2006). The study area lies in the limit between the proximal scour and sand ribbons sector, close to the Strait of Gibraltar, and the active contourite drift sector towards the NW (1 and 2 respectively in Fig. 1a). The proximal sector presents two channel-terrace systems, Northern and Southern, that connect with the middle slope contourite channels (Hernández-Molina et al., 2014). The active contourite drift sector contains the Faro-Cadiz sheeted drift that evolves towards the west into huge mounded drifts (e.g., Faro Drift) separated from the upper slope by the Alvares Cabral contouritic moat (Fig. 1a).

After the Miocene-Pliocene boundary, the Strait of Gibraltar became the gateway for the MOW into the Atlantic and the CDS recorded a series of tectonic pulses of different cyclicity that defined three evolutionary stages (Hernández-Molina et al., 2016): (1) Initial-drift stage (Pliocene, 5.33-3.2 Ma). Sedimentation was dominated by downslope processes, mostly turbiditic and debris flows while the progressive strengthening of a relatively weak MOW deposited large muddy sheeted drifts; (2)

Transitional drift stage (late Pliocene-early Quaternary, 3.2-2 Ma). This stage was characterized by interbedded contourites and turbidites, and occasional debrites, indicating a progressive intensification of the MOW strength; and (3) Growth-drift stage (after 2 Ma). Bottom-current activity prevailed over downslope-trending processes and shaped the present-day Gulf of Cadiz Contourite Depositional System (Hernández-Molina et al., 2016). This last Quaternary stage includes three main phases (Llave et al., 2001, 2006, 2007a,b, 2011). From the Early Pleistocene to the Mid-Pleistocene the MU core flowed along the base of the upper slope and mounded and sheeted drifts were deposited on the upper-middle slope boundary. Between the Mid Pleistocene and the Late Pleistocene, the MU core migrated northward due to changes in the tectonic activity of the Guadalquivir Bank and the diapiric ridges. During this stage, the main MOW flow that was previously conducted through five channels at the exit of the Strait of Gibraltar migrated to its present-day location along the Southern channel (Llave et al., 2019). These oceanographic changes resulted in the formation of mixed drifts, involving interaction between bottom current activity and gravitational processes that buried part of the sheeted and mounded drifts. During the Late Pleistocene to Holocene, a further northward migration of the MU core, that flowed with a more tabular character connecting with the Northern channel, resulted from tectonic movements in the Strait of Gibraltar and the reactivation of diapiric bodies, while the Southern Channel maintained its present-day position (Llave et al., 2019). During this stage the Gusano and Huelva channels were excavated on the proximal middle slope, and the mixed drifts were fossilized by a more aggrading plastered drift at the transition between the upper and middle slope. In this scenario, the MU core flow along the upper slope and upper terrace was favoured during warm highstand intervals, whereas the Lower core flow predominated along the middle slope, or even in deeper depths, during cold lowstand intervals (Llave et al., 2007a,b**;** Hernández-Molina et al., 2014; Lofi et al., 2016).

2.4. The Gulf of Cadiz upper slope

The upper slope along the Gulf of Cadiz has only been partially studied so far. The SE part of the northern Gulf of Cadiz upper slope is dominated by plastered contourite drifts incised by erosive scarps (Nelson et al., 1993, 1999; Llave et al., 2007b; Hernández-Molina et al., 2014; Brackenridge et al., 2018). The plastered drift along the Cadiz upper slope is composed of highly bioturbated silts to sandy silts and displays characteristic bi-gradational sequences (Brackenridge et al., 2018), and results from the interplay of bottom currents and turbidity currents/spillover processes as the main sediment supply (Nelson et al., 1993, 1999; Hernández-Molina et al., 2014; Alonso et al., 2016). The upper slope in this area is incised by numerous gullies that have been studied from a geostatistical point of view and related to gravitational flows since the Last Glacial Maximum, fed from the Guadalquivir and Guadalete rivers and mass wasting sediment supply (Fernández-Salas et al., 2015; Sánchez-Rubio et al.,

2015). Deposits belonging to regressive and lowstand systems tracts and accumulated during the Late Quaternary compose the middle to lower slope sequences (Rodero et al., 1999; Mestdagh et al., 2019, 2020). Towards the NW, the upper slope becomes the erosional northern wall of the Alvares Cabral contourite moat (Faugères et al., 1984; Llave et al., 2001; García et al., 2009; Roque et al., 2012; Fig. 1a). The westernmost upper slope, in the Portuguese margin, is dominated by the interplay between contouritic and turbiditic processes, with the incision of the Portimão, Lagos and Sagres submarine canyons in the contourite-dominated middle slope and down to the deeper basin (Mulder et al., 2006; Marchès et al., 2007, 2010; Fig. 1a).

3. Datasets, methodology and nomenclature

3.1. Datasets and methodology

This work analyses geophysical and geological datasets with different degrees of resolution (Fig. 1b). The regional bathymetry has a resolution of 500 m and has been obtained from the GMRT Map Tool (Ryan et al., 2009). The study area is covered with a high-resolution swath bathymetry data compiled along a series of cruises (SWIM compilation, Diez et al., 2005; CONTOURIBER, MOWER, INDEMARES) and gridded at a resolution of 50 m. Visualization and interpretation of bathymetric data were achieved using Fledermaus, Global Mapper and Mirone softwares. Airgun profiles were acquired during the CONTOURIBER and MOWER cruises. They are oriented NNW-SSE and WNW-ESE. Airgun 2-D seismic reflection profiles were acquired using different arrangements of 610-910 cu.in GI-airguns adapted to the water depth and quality of the signal. Shot frequency was 6 seconds and sampling rate of 0.5 ms. During the cruises navigation was controlled by the EIVA NaviPac and the vessel was positioned with a GPS dynamic system. The data were acquired with a three-channel (40 receivers/channel), 250 m long SIG streamer and recorded with a DELPH system. The vertical resolution of the seismic profiles is less than 10 m. Processing was performed with the Hotshots software and followed standard procedure, including equalization, low frequency filtering, band-pass filtering, stacking, and resampling to 1 ms. A grid of NE-SW and NW-SE-oriented multichannel 2-D seismic reflection profiles were provided by Repsol-YPF (S81). The entire seismic data set has been visualized and interpreted using the Kingdom Suite software.

High-resolution data (bathymetry and seismic profiles) have been analyzed in order to characterize the morphological features. To study the late Quaternary evolution of the upper slope, airgun seismic profiles have been correlated with previous regional stratigraphic studies based on the analysis of multichannel 2-D seismic reflection profiles (Hernández-Molina et al., 2016; Figs. 1b and 3). Two major unconformities (Mid Pleistocene Discontinuity, MPD and Late Quaternary Discontinuity, LQD) were identified after the Integrated Ocean Drilling Program (IODP) Expedition 339 and with the additional

information from well MPC-1 located in the upper slope of the studied area (Hernández-Molina et al., 2016). Despite the different resolution, these horizons can be translated to the dataset used in this study (Fig. 3). The seismic units correspond to the most recent Quaternary units (QIII) identified by Hernández-Molina et al. (2016) and QII (Llave et al., 2001, 2007, 2011; Brackenridge et al., 2013). The MPD has also been interpreted in previous studies (Fig. 3) as the Mid Pleistocene Revolution discontinuity (Llave et al., 2001, 2007, 2011; Hernández-Molina et al., 2003, 2006; Brackenridge et al., 2013), D2 (Marchès et al., 2010) or H4 (Roque et al., 2012). The discontinuity bounding units Q5 and Q6 correlates with discontinuities LQD (Hernández-Molina et al., 2016), D3 (Marchès et al., 2010) and H5 (Roque et al., 2012). The analysis of multichannel seismic profiles has allowed controlling the slope sedimentary evolution, and to analyze the structural features affecting the sediment record. The analysis of high-resolution seismic profiles (airgun) has allowed a more detailed characterization of the geometry, distribution and character of the seismic units in a temporal scale from the Middle Pleistocene to present. The penetration of these profiles and the presence of the bottom multiple reflection only allows a detailed description of the most recent unit, Q6. In addition, the multichannel seismic profiles have been used to obtain isochore maps of the seismic units identified in this work.

3.2. Nomenclature

Morphological features are identified based on their morphometric parameters, spatial distribution and seismic characteristics. Contouritic morphological features (contourite drifts, channels, furrows, terraces) follow the nomenclature established by Faugères et al. (1993a,b, 1999), García et al. (2009) and summarized by Rebesco et al. (2014). Sediment waves are identified based on the bathymetry and on their internal geometry observed in seismic profiles, with changes in the thickness of individual seismic layers (Berndt et al., 2006; Viana, 2009). Mass transport deposits (MTDs) are defined based on their seismic signature including a basal erosional surface, top hummocky relief at the top and internal chaotic to transparent seismic facies (Shanmugam, 2007; Posamentier and Martinsen, 2010; Shanmugam, 2012; Ruano et al., 2014). Mass movement erosional features include submarine valleys and escarpments. Upper slope valleys are classified as gullies, based on their downslope trend (Fedele and Garcia, 2009), and their dimensions -an order of magnitude smaller than submarine canyons (Field et al., 1999; Rinke-Hardekopft et al., 2018). Shelf-edge escarpments are interpreted as slide scars based on their arcuate-linear shape and their step-like profiles that truncate underlying seismic reflections (Mulder and Cochonat, 1996; McAdoo et al., 2000; Twichell et al., 2009; Piper et al., 2012; García et al., 2016). Fluid-escape features are defined by their circular- to elliptical plan-view shape in the seafloor (Hovland and Judd, 1988; Schattner et al., 2018), their characteristic seismic signature (Cartwright and Santamarina, 2015) and based on previous descriptions (Baraza and Ercilla, 1996; Baraza et al., 1999; León et al., 2010).

4. Results

4.1. Physiography and morphology

4.1.1. Physiography

The continental margin close to the Strait of Gibraltar extends for about 100 km with a SSE-NNW-orientation, turning to a ESE-WNW orientation off the Guadalquivir river mouth (Figs. 1a and 4a). The continental shelf-edge in this proximal part of the margin is relatively smooth along the study area and occurs at water depths of 110-130 m. The upper slope reaches depths of 390-480 m, extending deeper in the area off Cadiz, to the east of the Cadiz diapiric ridge (green profiles in Fig. 4b). The upper slope profile is flat to convex-upward in the south and central part of the study area and flat to concave-upwards in the north (Fig. 4b). A marked change in the slope gradient marks the transition between upper and middle slope except for the central part of the study area, where the transition is smooth and bulge-shaped (Fig. 4b).

In the studied sector (Figs. 4 and 5) the physiography of the upper and middle slope allows the establishment of three areas with distinct bathymetric profiles: Southern, Central and Northern (Fig. 4a). The Southern area displays a featureless upper slope with a convex-upwards profile and widths of about 16 km (Fig. 4b). Its lower limit, at about 500 mwd, connects with a narrow and steep ramp (2 km wide and 3º slope gradient) that connects with the Northern contourite channel in the middle slope. The channel is incised at the western part of a 35 km wide terraced platform at 670-770 mwd that limits towards the NW with the Cadiz and Huelva contourite channels (Fig. 4a). The Central area shows a relatively flat upper slope profile, with width increasing towards the north from about 5 km to a maximum of 22 km, whereas the steepness decreases from about 3° to 1.2° (Fig. 4b). The connection with the Northern channel in the middle slope occurs at water depths of about 500 m through a steep ramp (< 1 km wide and up to 7°) (Fig. 4b). The Northern area has a convex-upward upper slope with a width that decreases towards the north to about 12 km, and the steepness ranges between 1 and 2.2° (Fig. 4b). It connects smoothly with the middle slope at water depths of 400-450 m. The middle slope has a lower gradient (less than 0.7º) and connects with the Faro-Cadiz sheeted drift at the eastern side of the Cadiz diapiric ridge. The sheeted drift is bounded towards the west by the Tofiño contourite channel and the Cadiz diapiric ridge and to the south by the Huelva contourite channel (Fig. 4b).

4.1.2. Morphological features

A range of morphological features have been identified in the study area, and are classified according to their origin as (i) structural, including the diapiric highs and ridges, (ii) contouritic,

represented by a large plastered drift, sediment waves and contourite channels, (iii) gravitational, including escarpments and gullies , and (iv) fluid-escape related features.

(i) Structural features. The Cadiz diapiric ridge (CDR; Figs. 4a and 5b) is the main outcropping diapiric feature in the study area. The ridge has an N-S to NNE-SSW orientation. Its northern part outcrops in the middle slope close to the limit with the upper slope in the Northern area and is dissected by the Gusano and Tofiño contourite channels. The southern part lies between the Huelva and Cadiz contourite channels. The ridge has isolated peaks up to about 200 m in height, with a minimum water depth of 320 m.

(ii) Morphological features of contouritic origin. The *plastered drift* that makes up the upper slope (Hernández-Molina et al., 2014; Brakenridge et al., 2018) has a typical convex-upwards morphology, and the rest of morphological features are overprinted on its relatively flat surface (Fig. 4). *Sediment waves* are superimposed on the plastered drift in the Northern area. They are oriented SE-NW to S-N (parallel to slightly oblique to the isobaths; Fig. 5c). Individual crests are around 0.5-1 km long, and the wavelength averages 0.5 km. Sediment waves are asymmetric, with steeper downslope-facing flanks (up to 2.4º) and almost flat upslope-facing flanks. C*ontourite channels* (Northern, Southern, Cadiz, Huelva, Gusano and Tofiño) are major erosional features composing the Gulf of Cadiz Contourite depositional system (Hernández-Molina et al., 2003; García et al., 2009; Lozano et al., 2020). The upper slope connects with the Northern channel defined by Hernández-Molina et al. (2014) at 530-580 mwd in the Southern and Central areas (Fig. 5b). The Northern channel joins the Huelva and Cadiz contourite channels along the distal limit of the upper slope and is absent in the Northern area of this study (Fig. 4a).

(iii) Gravitational features. *Shelf-edge escarpments* occur in the Central and Northern areas (Figs. 5b and 5d). A prominent arcuate escarpment at the shelf-edge of the Central area is 20 m high and about 4 km long. Basinwards of the escarpment the bathymetric profile is concave-upwards (Fig. 5d). Linear, up to 8 m high N-S to NW-SE-oriented escarpments occur along the shelf-edge of the Northern area. A 12 km long linear escarpment 30 m deep and 5º steep occurs in the Southern area at the limit with the Northern channel, where the channel trend changes from SSE-NNW to SE-NW (Fig. 5b). G*ullies* occur on the Central and Northern areas (Fig. 5b) Gullies in the Central area extend from 205-250 mwd, below the continental shelf-edge, to the rim of the Northern channel. Gullies are generally asymmetric, with steeper and higher NW walls and present V-shaped profiles (Fig. 5e), 12-20 km long, 2-25 m deep and 0.2-1 km wide. Their orientations range ENE-WSW to NE-SW, they are spaced 0.4-2 km and display a dendritic convergent pattern (Fig. 5b). Gullies are less common in the Northern area. Their heads are located at 205-240 m, and they terminate at water depths of 405-415 m, in the

relatively flat Faro-Cadiz sheeted drift on the middle slope (Fig. 5b). They are smaller (5.5-9.5 km long; 0.2-0.4 km wide and 1-3 m deep) than in the Central area and have asymmetric U- or V-shaped profiles (Fig. 5e). They are E-W to ENE-WSW-oriented, with linear trends and they occur as individual features, spaced 0.3-1 km.

(iv) Fluid-escape features are circular- to elliptical-shaped depressions identified in the deeper part of the upper slope in the Central area close to the rim of the Northern channel (Fig. 5b). They are up to 1.5 km wide and 70 m deep. Most of them are aligned along the axes of gullies and their long axis have similar orientations (roughly NNE-SSW) whereas others occur in inter-gullies areas and are oriented parallel to the bathymetric contours.

4.2. Seismic analysis

4.2.1. Acoustic basement and structural features

The topography of the acoustic basement in the study area is highly irregular, with depths ranging between 0.5 and 3.7 s two-way travel time (TWTT; Fig. 6a). A prominent acoustic basement high in the SE part of the study area delimits a NE-SW-trending depression extending from the present-day continental shelf to the middle slope. Basement highs coincident with the Cadiz and Guadalquivir diapiric ridges delimit a second NE-SW oriented basement depression that opens towards the SW. Other minor basement highs roughly coincide with the present-day shelf-edge, whereas most of the upper slope is characterized by basement highs delimiting irregular depressions.

Diapir tops are spatially associated to the basement topography (Fig. 6a). Apart from the outcropping diapiric ridges, most diapirs are buried and their tops are aligned with two predominant orientations: NE-SW and NW-SE. The top ofmost of the upper slope buried diapirs as well as the two outcropping diapiric ridges are oriented NE-SW to ENE-WSW. Below the distal limit of the Central area a NE-SW diapir and its associated faults reach the seafloor. Columnar zones of acoustic amplitude anomalies and truncated seismic reflections connect vertically withthe circular- to elliptical-shaped fluid-escape depressions on the present-day sea-floor and in the seismic record (Figs. 5b, 7b and 8b). Some other diapirs are aligned in a perpendicular NW-SE to WNW-ESE direction (Fig. 6a). They occur in the present-day Cadiz contourite channel, in the upper slope of the Central area (where the heads of many gullies occur), on the upper slope at the limit between the Northern and Central areas (coinciding with the distal end of many gullies), and at the NW side of the outcropping Cadiz diapiric ridge, where the Gusano channel is excavated. Faults are widespread features in the sedimentary record of the Cadiz upper slope (Figs. 6b to 10). They are mostly normal faults that are rooted in the diapirs, both at their tops and flanks and can be defined as extensional crestal faults (Jackson and

Hudec, 2017). Faults rarely reach the seafloor, and are often associated to the gullies and to the fluid-escape features (Figs. 6b to 10).

4.2.2. Seismic stratigraphy

The two major seismic discontinuities (MPD- Mid Pleistocene Discontinuity and LQD- Late Quaternary Discontinuity) define two major late Quaternary units , following the most recent regional nomenclature proposed by Hernández-Molina et al. (2016) (Figs. 3c and 3d): a) Seismic Unit Q5 (MPD-LQD, subdivided into three sub-units, Q5-a to Q5-c) and b) Unit Q6 (LQD-Present, composed of four sub-units, Q6-a to Q6-d). All discontinuities are better defined in the proximal upper slope by pronounced changes in the frequency and acoustic amplitude of reflections. The character of units and sub-units and the main seismic features are shown in Figures 7 to 11. The topography of the basal discontinuities bounding each unit and their thickness distribution are shown in Figure 12.

a) Seismic Unit Q5: MPD-LQD

The seismic configuration of Q5 unit shows a mostly aggrading stacking pattern with parallel stratified reflections of medium to high amplitude and interlayered wavy-chaotic packages with disrupted reflections, in the Southern area (Figs. 7 to 9). The Central area shows layered and wavy-chaotic disrupted reflections that display a progradational configuration towards a paleo-channel about 6 km to the east of the present-day Northern channel (Fig. 10). In the Northern area, Q5 mostly presents parallel stratified reflections. V- or U-shaped erosional depressions are mostly identified in the seismic lines parallel to the bathymetric contours and occur mostly associated to diapir-related faults. They are more common in the top of the unit where they occur around diapiric highs in the Southern area and show vertical migration towards the NW (Fig. 8a). Q5 is deformed by the NE-SW and the NW-SE trending diapiric alignments and related faults, with upward tilting and thinning towards the diapiric highs (Figs. 7 to 11).

The overall distribution of Q5 is patchy, with depocenters up to 360 ms TWTT thick located between diapir highs and pronounced decreases in thickness towards the top of isolated diapiris and diapiric ridges (Fig. 12a). Depocenters are smaller in the Northern area, whereas the Central and Southern areas contain wider and thicker depocenters (230-360 ms TWTT) on the present-day shelf-edge and upper slope. The geometry of the seismic unit Q5 is tabular in the Southern and Central areas (Figs. 9 and 10). In the Central area, thickness decreases in a paleo-channel displaced about 6 km to the east of the present-day Northern channel. In the Northern area (Fig. 11), the geometry ranges from wedge-shaped, with higher thickness towards the proximal areas of the slope to lens-shaped, with minimum thickness towards the flanks of diapiric bodies. During deposition of Q5 the topography

of the upper slope changed significantly (MPD base surface to LQD base surface; Fig. 12b to 12d) producing: a) the infilling of the NE-SW-trending depressions at the SE of the study area and between CDR and GDR; b) the infilling of small depressions at the present-day base of the upper slope; c) the advance of the continental shelf-edge to positions similar to the present-day.

Three sub-units compose the seismic unit Q5 (Q5-a, Q5-b and Q5-c, from older to younger). The three sub-units have similar distribution patterns, with a progressive displacement of depocenters towards the present-day shelf-edge (Figs. 7 to 11). Q5-a (MPD-5b discontinuities) has mid to high acoustic amplitude in generally parallel layered reflections. It displays maximum thickness in the present-day shallower upper slope of the Central and Northern areas, and in the middle upper slope of the Northern area. Q5-b (5b-5c discontinuities) has lower acoustic amplitude than Q5-a and its depocenters are aligned along the present-day shallower upper slope of the Southern and Central areas. Q5-c (5c-LQD discontinuities) is characterized by low-acoustic ampitude at the base that become higher towards the top. Its thickness is higher along the shallower upper slope of the Central area, and on the midddle upper slope of the Southern area.

b) Seismic Unit Q6: LQD-seafloor

The seismic configuration of Q6 shows layered reflectors locally interbedded with packages of disruptedreflectionss in the Central and Northern areas, and lower acoustic amplitude than Q6 (Figs. 7 to 11). Q6 is widely deformed by NW-SE buried diapir alignments and the outcropping diapiric ridges, but deformation by NE-SW-oriented ones is drastically diminished. The NW-SE-oriented diapir alignment located in the limit between the Central and Northern areas only deforms Q6, whereas the underlying unit Q5 is not affected. Seismic unit Q6 is much less deformed by diapir-related faults than Q5, in particular towards the top (Figs. 7 to 11).

The overall distribution of Q6 is different from the underlying Q5, showing greater thickness (up to 660 ms TWTT) and a more homogeneous distribution (Fig. 12c). The main depocenter locates below the present-day shelf edge, at the limit between the Northern and Central areas. Thickness decreases towards the CDR and GDR and the buried NW-SE-oriented diapiric alignments at the eastern side of the CDR. The deposition of Q6 resulted in the growth of the present-day upper slope to the NE rim of the Northern contourite channel, that presents minimum thicknesses (<200 ms TWTT). Since the LQD, the main changes in the topography include the infilling of previous depressions, the excavation of the Gusano contourite channel to the north of the CDR and the incision of gullies (Fig. 12d).

Q6 is composed of four sub-units (Q6-a to Q6-d, from older to younger). Whereas the four sub-units show a similar pattern of deformation, their distribution, geometry and internal configuration have important differences and will be described individually.

Q6-a sub-unit (LQD – 6b discontinuity) has a tabular geometry with layered reflections in the Southern area. The unit displays increased thickness and disrupted reflections in the footwall side (basinward) of a set of diapir-related faults (Fig9 8). It displays maximum thickness of about 0.12 s TWTT in the Central area upper slope at the footwall side of a set of diapir-related faults. Thickness is significantly low in the shallower upper slope and particularly at the proximal middle slope, at the eastern side of a paleo-channel, slightly displaced to the west of the present-day Northern channel (Fig. 10). V- and U-shaped depressions occur both within the sub-unit and incised in the top discontinuity, generally associated to faults (Figs. 7b and 8a). Towards the Northern area, Q6-a shows layered reflections with V-and U-shaped depressions in the deeper areas between diapirs, and the thickness is generally low (Figs. 7 and 8). This sub-unit is generally thin with maximum thickness of about 180 ms TWTT in a wide depocenter on the deeper part of the present-day upper slope.

Q6-b (6b-6c discontinuities). This sub-unit displays similar seismic characteristics as Q6-a in the Southern area, but the depocenter is slightly displaced upslope (Fig. 9). In the Central area the upslope displacement of the deposition is more evident as well as a thickness decrease below the present-day Northern channel (Fig. 10). In the Northern area the base of the sub-unit has a transparent to chaotic character with disrupted reflections (Figs. 7 and 11). The sub-unit presents numerous small V-shaped depressions in the deepest part of the upper slope and thickness increases significantly between diapiric highs.

Q6-c (6c-6d discontinuities). This sub-unit is mostly layered in the entire study area. The top boundary shows erosional truncations in the Southern area. It presents few V- or U-shaped depressions in the Central area, in most cases associated with faults (Figs. 7 and 10). In this area, Q6-c displays mounded configurations with upslope progradation on the deeper part of the upper slope, at the foot wall of a set of diapir-related faults (detail in Fig. 10). In the Northern area V- and U-shaped depressions only occur at the top boundary (Fig. 11). Q6-c is relatively thin, particularly in the Southern area. Maximum thickness (around 0.2 s TWTT) occur in the Central area where the distribution is affected by the diapiric highs. The Northern area shows depocenters in the depressions between diapiric highs.

Q6-d (6d discontinuity- seafloor) displays a stratified character with very low acoustic amplitudes in in the Southern and Central areas (Figs. 9 and 10). In the Central area layered reflections are cut by V-shaped depressions along the entire sub-unit that show a NW upward migration (Fig. 8). Q6-d displays

a distinctive wavy-chaotic seismic character with disrupted reflections at the shallower upper slope in the Northern area and chaotic-transparent in the deeper parts where it connects with the middle slope (Fig. 11). The main depocenters occur at shallower depths than the previous sub-units, along the present-day shelf-edge in the Central area.

5. Discussion

The physiographic, morphologic and seismic stratigraphic analysis presented in the previous sections allow inferring the sedimentary processes that have shaped the upper slope and proximal middle slope of the Gulf of Cadiz in the study area and to analyze their evolution since the MPD based in chronostratigraphic correlations. Two major factors (sea-level changes and episodic tectonic activity) are proposed to have controlled the sedimentary evolution of this part of the margin.

5.1. Sedimentary interpretation and chronostratigraphic correlations

Based on the results of this work and on previous published literature (Nelson et al., 1993, 1999; Llave et al., 2007b; Hernández-Molina et al., 2014; Brackenridge et al., 2018; Mestdagh et al., 2020), the upper slope is characterized by plastered drift deposition since the MPD, as suggested by the parallel-stratified seismic character of high lateral continuity, aggrading pattern and tabular to slightly mounded geometry (Faugères et al., 1999; Hernández-Molina et al., 2006; Van Rooij et al., 2010). At the connection with the middle slope, the plastered drift limits with the Northern channel (Hernández-Molina et al., 2014) that can be defined as a contourite channel based on the along-slope trend and the presence of truncated reflections (Figs. 4, 5 and 9 to 11; Faugères et al., 1999).

The LQD marks a change in the stacking pattern as the plastered drift-contourite channel system migrated towards the SW, the plastered drift increased in thickness and the contourite paleo-channel increased its incision in the proximal middle slope (Fig. 12). The chronostratigraphic correlation allows interpreting the sedimentary evolution in relation with the two main discontinuities, the MPD and the LQD. The MPD (base of seismic unit Q5) is a discontinuity that exhibits different stratigraphic character in the Gulf of Cadiz continental slope, such as an erosive hiatus, a condensed section or a section with reduced sedimentation rate in different locations, related to a tectonic event related with tectonic shortening and gravitational spreading, with an age around 0.7–0.9 Ma (Hernández-Molina et al., 2016; Lofi et al., 2016). It also corresponds to the Mid Pleistocene Revolution (MPR) in the quaternary climatic discontinuity, related to the first important cold event and associated sea-level fall in the Pleistocene (Llave et al., 2001, 2004; Hayward et al., 2005; Head and Gibbard, 2005; Ehlers and Gibbard, 2007) and the MOW enhacement coeval with an increase in the sedimentation rates in the Gulf of Cadiz (Llave et al., 2011; Roque et al., 2012; Hernández-Molina et al., 2016). LQD corresponds to a hiatus in the time window of 0.3–0.6 Ma (Hernández-Molina et al., 2016; Lofi et al., 2016)

498 characterized in seismic profiles of the middle slope contourite drifts by an angular unconformity on
499 the basin margins and the flanks of the topographic highs that changes laterally to concordant
500 relationships in the middle of the basins (Hernández-Molina et al., 2016). This discontinuity has been
501 associated with a lowering of the sea level (Marchés et al., 2010) and an strenghtening of the MOW
502 circulation in the middle continental slope (Roque et al., 2012).

503 *5.2. Influence of sea-level on sedimentation: paleoclimatic and paleoceanographic implications*

504 Sea-level change is a crucial factor controlling bottom current sedimentary processes (Rebesco et al.,
505 2014). The stacking pattern of the plastered drift and the adjacent Northern contourite channel allows
506 inferring the paleoclimatic and paleoceanographic conditions that influenced their evolution. The
507 results of this study suggest that the plastered drift grew under the activity of a weak ENACW flow,
508 whereas the contourite paleo-channel evolved by the erosive effect of the MOW, during regressive
509 and lowstand sea-level stages. Lowered sea-levels during glacial stages are characterized by enhanced
510 deep circulation that produces a more intense and deeper ML in the Gulf of Cadiz (e.g. Llave et al.,
511 2006, 2007, Toucanne et al., 2007; Marchès et al., 2010; Lofi et al., 2016) and even the probable
512 dissappearance of the MU (Roque et al., 2012). Since the study area is located at the present-day
513 interface between the MOW and the ENACW (Fig. 2), the deepening of the MOW would have left the
514 entire upper slope under the effect of the ENACW during the lowstands of the asymmetric glacial
515 cycles. This scenario would last a longer period of time compared with the highstand situation in which
516 the MOW covers the upper slope, as at present. Furthermore, it is during sea-level lowstands that the
517 sediment supply from fluvial discharge and continental shelf, required to produce significant plastered
518 drift growth in this area is enhanced (Rodero et al., 1999; Mestdagh et al., 2019). Under this
519 assumption, sub-unit boundaries within Q5 and Q6 units can be tentatively linked to the 100 ky
520 Quaternary climatic oscillations as defined by the benthic $d^{18}O$ isotopic curve of Lisiecki and Raymo
521 (2005) (Fig. 3d).

522 V- and U-shaped depressions not related to diapir-associated faults are widespread along the seismic
523 sub-units (Fig. 3d) and we interpret them as paleo-gullies, based on the truncated reflections in their
524 flanks, the local presence of lateral deposits (levees) and their morphological resemblance with the
525 present-day gullies. Their occurrence supports that the bulk of the plastered drift growth affected by
526 gullies incision occurred during glacial climatic stages, assuming a genetic link between gully formation
527 and sea-level lowstands, as documented in other continental margins (Field et al., 1999; Spinelli and
528 Field, 2001). Gullies migration suggests southeastward bottom current activity, coincident with the
529 circulation pattern of the ENACW. Migrating trends upstream of the bottom currents have been
530 reported in modern sea-floor (Campbell and Mosher, 2016) and in the sedimentary record (Sansom,

2018; Fonnesu et al., 2020). Recent three-dimensional flume-tank experiments have explained how low density turbidity flows can be deviated by weak along-slope currents and demonstrate that the direction of migration of gravitational channels is opposite to the direction of the bottom current interacting with them (Miramontes et al., 2020). Therefore, we propose that diffuse, sheet-like turbidity currents presumably originating on the shelf as proposed by Lonergan et al. (2013) or alternatively low density cascading water flows (Micallef and Mountjoy, 2011) were deflected by a weak along slope current forming asymmetric gullies with their axes migrating up-current. During transgressive and highstand stages the study area is, in contrast, under the influence of the MOW (Sánchez-Leal et al., 2017). In these conditions, such as present-day, the plastered drift is reworked by the northeast-trending flow, most gullies become inactive and the contourite channel is strongly affected by the MU flow. The vertical shifts along the glacial/interglacial cycle of the interface between the Mediterranean Water and the overlying ENACW (Fig. 2; Hernández-Molina et al., 2014, 2016; Sánchez Leal et al., 2017) and the high variability of the water masses dynamics (Bellanco and Sánchez-Leal, 2016; Roque et al., 2019) may also have favoured the incision of gullies.

LQD marks a change in the paleoclimatic and paleoceanographic conditions that influenced the evolution of the plastered drift. After the initial stage of plastered drift growth and upslope migration (Q6-a and Q6-b), a stage of aggradation occurred with deposition of the two more recent sub-units Q6-c and Q6-d (Fig. 10). The most recent sub-unit Q6-d is incised by markedly asymmetric gullies displaying northwestward migration in the Central area, which denotes increased bottom current influence on the gravitational sediment transport. The predominance of contouritic processes versus gravitational processes during deposition of this last sub-unit is also responsible for the inactivation and infilling of many buried upper slope gullies. The mounded body infilling the erosional scour at the shelf edge (Fig. 9b) suggests bottom current acceleration by the interaction with the escarpment associated to the escarpment (e.g., Rebesco et al., 2014; Juan et al., 2020). The deposition of a sediment wave field in the Northern area, which constitutes the main morphological difference with the Central area (smooth inter-gullies areas; Fig. 5), is interpreted as a combination of sediment deformation related to unconfined turbidite flows (Ercilla et al., 2002; García et al., 2012) and the intensified effect of bottom currents (Faugères et al., 2000a,b; Gonthier et al., 2002), as indicated by the orientation (parallel to oblique to bathymetric contours and to the bottom current direction) and the upslope migration of sediment waves (Masson et al., 2002; Wynn and Stow, 2002). Bottom currents intensification after the LQD may have been favored by the prevalence of glacial cycles with longer and warmer interglacials (Roque et al., 2012), and is consistent with the transition from sandy sheeted drifts to muddy sheeted and mounded drifts observed in the middle slope (Hernández-Molina et al., 2016). Sediment waves development may also have been favored by high-energy processes

(eddies, internal tides or internal waves) associated to water masses interfaces (Cacchione et al., 2002; Youbin et al., 2008; Lamb, 2014) as their location also coincides with the interface between the ENACW and the MU (Fig. 3; Hernández-Molina et al., 2014, 2016; Sánchez-Leal et al., 2017: Roque et al., 2019).

5.3. Episodic pattern of tectonic deformation: Influence of tectonic deformation on sedimentary processes

The MPD marked a phase of tectonic activity in the region that resulted in the formation of erosional surfaces close to diapirs and basement highs (Lofi et al., 2016; Hernández-Molina et al., 2016). Tectonic activity evolved episodically since the MPD as shown by changes in the deformation of seismic units and sub-units and the different development of morphological features in the seismic record. During deposition of Q5 (MPD-LQD) sedimentation was controlled by the activity of marly and salt diapirs rooted in the AUGC, under a compressive regime between Iberia and Africa (Maestro et al., 2003; Medialdea et al., 2004), as indicated by the correlation between diapir distribution (Fig. 6) and the thickness of seismic unit Q5 which infills depressed areas delimited by diapiric highs (Fig. 12a). The upward deformation and thinning of sub-units indicate that diapir activity was coeval to Q5 deposition.

A prominent change of depositional conditions during deposition of sub-units Q6-a and Q6-b (LQD-discontinuity 6c) is inferred by the absence of significant thickness variations in relation to NE-SW-aligned buried diapirs in the upper slope, that would have become inactive (Figs. 7 to 11). The decrease in diapiric activity in the upper slope may be coeval with the inactivation of some diapiric ridges in the middle slope (Hernández-Molina et al., 2016). In contrast, the outcropping Cadiz diapiric ridge (CDR) and the buried NW-SE-aligned diapirs continued or started to deform the sedimentary units. In this scenario, mass flow deposits were formed at the foot of diapir-related faults (Figs. 9and 10).

Tectonic activity can be related to the WNW-ESE strike-slip faults recognized in the Gulf of Cadiz, with a dextral movement (Terrinha et al., 2009; García et al., 2009; Bartolomé et al., 2012; Martínez-Loriente et al., 2014). During this stage (Q6-c) sedimentation changed drastically as it lacks most of the structural imprint in the form of faults related to diapirs, except for the southernmost part of the study area. In this scenario, mass flow deposits were formed at the foot of the faults. Although the continuous uplift of NW-SE-oriented diapirs is suggested by the thinning of the sub-unit Q6-c on top of the diapiric highs, it is less significant than in the other stages (Figs. 7 to 11). After the scarce diapiric activity in the previous phase, deformation in sub-unit Q6-d is related to the activity of the outcropping diapiric ridges and the buried NW-SE-oriented diapirs. This activity may explain the

instability event that created escarpments and the erosion of the previous sub-unit in the Southern area (Fig. 10). The last sub-unit of Q6 (Q6-d; discontinuity 6d-surface) is only deformed by the CDR and one of the NW-SE-oriented diapir alignments located in the area that limits the Central and Northern areas. The outcropping Cadiz and Guadalquivir diapiric ridges are the only NE-SW structures that show significant activity after the MPD. This can be explained by changes in the activity of faults, leading to a northwestward displacement of tectonic activity after the MPD, but can be also favoured by downbuilding (passive diapirism), that allows the continued growth of a diapir after it pierces the surface, while sedimentat accumulates at its flanks (Barton, 1933; Jackson and Hudec, 2017). The relative high/low sedimentation rate around/on the diapiric ridges, caused by the activity of bottom currents, would originate the differential sedimentary burden, contributing to diapir growth.

Episodic tectonic deformation has influenced the sedimentary processes since the MPD, including: 1) bottom current deposition/erosion; 2) gravitational processes; and 3) fluid escape processes.

5.3.1. Tectonic influence on bottom current processes

Between the MPD and the LQD (seismic unit Q5) the plastered drift was deposited on the upper slope, consisting of quite tabular and aggrading sub-units. Tectonic activity controlled the accommodation space, as indicated by the distribution of depocenters in the depressions between diapiric bodies (Fig. 12a). The paleo-channel was located about 6 km to the east from the present-day Northern channel, whereas a wide terrace formed by gently upslope-prograding reflections was deposited on the middle slope (Fig. 10a).

After the LQD, a number of processes including paleo-channel migration towards its present-day position, the narrowing and/or westward displacement of the middle slope terrace and the basinward migration of the plastered drift (Figs 7 to 12) could be related to tectonic activity of diapir-related faults coeval with LQD. Diapiric activity uplifted the area bounding the Central and Northern areas. The terrace-paleo-channel system migrated to a more distal position as it adjusted to the new margin morphology, in a cooler climatic regime with probably deeper MOW/ENACW circulation. After the LQD the plastered drift growth increased and depocenters migrated downslope, initially in the Central area (sub-unit Q6-a; Fig. 10) and later in the Northern area (sub-unit Q6-b; Fig. 11). The plastered drift growth is responsible for the unusual convex-upwards profile of the upper slope in the Central area (Fig. 4b), that differs from the concave-upwards profile with marked gradient change between the upper and middle slope in the rest of the margin. These lateral differences on the overall plastered drift morphology could be explained by the relative higher dominance of gravitational processes over bottom current processes along the upper slope. After the main pulse of basinward migration,

depocenters show a progressive displacement towards shallower positions (Figs. 10 and 11), in agreement with the typical evolution of plastered drifts (Rebesco et al., 2014).

5.3.2. Tectonic influence on gravitational processes

Diapiric activity may be invoked as a trigger for mass-wasting processes, as uplift and faulting associated with diapir intrusion may produce fracture and oversteepening of the slope that leads to instability and failure (Cashman and Popenoe, 1985; Hampton et al., 1996). In the Cadiz upper slope, arcuate- and linear-shaped escarpments along the shelf-edge can be related to the activity of a buried diapir high and associated normal faults identified below in the sub-surface (Fig. 6). Moreover, the increase in upper slope gradient induced by diapirs uplift can further favor gully incision (Mountjoy et al., 2009; Argnani et al., 2011; Alves et al., 2014) as it is observed in the Central area. Furthermore, diapir-rooted faults may produce topographic steps or lips along which gravitational flows are channelized (Vargas et al., 2012; Micallef et al., 2014; Pellegrini et al., 2016; Tsai et al., 2018). This is proposed to be the case of the gullies in the older seismic unit Q5, particularly in the Central area, based on their spatial correlation with faults (Figs. 7 and 8). Subsequently, several Late Pleistocene and Holocene reactivations of upper slope diapirism (Vázquez et al., 2010; Fernández-Puga et al., 2014) could have favored continued gully development (Figs. 7 to 11), particularly in sub-unit Q6-c where gullies are less developed and only occur associated to diapiric highsic movements in the southern part of the study area (Fig. 8a). Uplift of the Cadiz diapiric ridge forced the confinement of mass transport deposits that occur as transparent to chaotic deposits in the most recent sub-unit Q6-d on the shallower upper slope and at the limit between upper and middle slope in the Northern area (Fig. 11), and may also have limited the gullies development in this area due to the decrease of the slope gradient.

5.3.3. Tectonic influence on fluid escape processes

Fluid-escape features include circular- to elliptical-shaped depressions on the seafloor and depressions in the seismic records (Figs. 7b and 8b). Depressions are distinguished from gullies based on the circular- to elliptical plan-view shape for the seafloor features (Hovland and Judd, 1988; Schattner et al., 2018), and the occurrence of acoustic amplitude anomalies in columnar shape and bright spots in the seismic record (Plaza-Faverola et al., 2011; Cartwright and Santamarina, 2015; Maestrelli et al., 2017). Indeed, evidences for fluid-escape related to active diapirism have been found in the Gulf of Cadiz, resulting in the formation of pockmarks and blind valleys (Medialdea et al., 2009; León et al., 2010). Fluid-escape may be controlled by diapiric faults, that form preferential conduits (Casas et al., 2003; Somoza et al., 2003; Medialdea et al., 2004; Fernández-Puga et al., 2007; Medialdea et al., 2009;

Schattner et al., 2018). Fluid-escape features in the deeper upper slope of the Southern area (Figs. 5b, 7a and 8b) are located on top of buried diapir alignments that became inactive during the LQD, although recent fluid-escape activity has been demonstrated by the identification of seeping bubbles above some of the depressions (Baraza and Ercilla, 1996).

6. Summary and conclusions

The Cadiz upper and proximal middle slope have evolved since the Middle Pleistocene under the major control of the tectonic activity, responsible for diapiric movements and associated faults, and sea-level changes, that have determined the interplay between downslope (gravitational) and along-slope (bottom current related) sedimentary processes. Two evolutionary stages are proposed (Fig. 13):

a) Small, plastered drift deposition under the activity of NE-SW-oriented diapiric ridges (MPD-LQD; Fig. 13a). A plastered drift developed in the Central area during the regressive and low sea-level stages of glacial cycles, as the MU deepened and the upper slope was swept by the southeastward flow of the ENACW. In the northern area, small patchy plastered drifts were deposited. The activity of NE-SW-oriented diapiric bodies produced their deformation and the occurrence of mass flow processes such as slope instability and gullies incision. A contourite terrace associated to the main MOW flow was formed at the western side of the paleo-contourite channel.

b) Plastered drift growth and upslope migration of sedimentation under the activity of NW-SE-oriented buried diapirs (LQD-present; Fig. 13b). At the LQD, most of the NE-SW-aligned buried diapirs in the Central and Northern areas became inactive, but the activity of the outcropping diapiric ridges and the buried NW-SE-aligned diapirs resulted in deformation of the deposits by faults and the occurrence of mass-transport deposits related to slope instability. The results of this work suggest that adjustment to the tectonic uplift of the area bounding the Central and Northern areas produced the migration of the upper slope plastered drift and the terrace-channel system in the middle slope towards its present-day position. The plastered drift developed significantly during this stage, probably as result of deep currents enhancement and increased sediment supply during regressive and low sea-level stages. Seismic unit Q6 records the upslope migration of the plastered drift. Tectonic activity was not continuous, but a period of "quietness" led to low deformation and gully incision during deposition of sub-unit Q6-c. This quiet period was followed by renewed tectonic activity of the outcropping diapiric ridges and the NW-SE-oriented buried diapiric bodies, which produced instability events.

This work reveals a progressive change in diapiric activity, both in the orientation of active diapir alignments along time and in the overall northwestward migration of deformation that is related with the dynamics of the Allocthonous Unit of the Gulf of Cadiz. Diapiric deformation produced changes in

the accommodation space that was infilled by the predominant contouritic sedimentation, but also changes in the upper slope physiography, that led to the occurrence of a variety of downslope mass transport processes. The most important implications are: I) gullies incision favoured by the increase in the slope and controlled by diapir-related faults, affected along their development by the southeastward bottom currents; II) mass transport processes related to the activity of diapir-related faults and probably further facilitated by the erosive effect of the bottom current; III) fluid-escape features associated to faults rooted in the diapirs; IV) changes in the bottom current distribution, forced to adjust to tectonically-induced changes in the margin morphology.

The results of this work highlight the two-ways-interaction between diapiric activity and erosive/depositional bottom current related processes. Sedimentation in the Cadiz upper slope since the Middle Pleistocene is strongly controlled by the activity of buried diapirs that accommodate the ongoing deformation of the Allochtonous Unit. The continuous deformation of the outcropping diapirs after the LQD, when most of the buried NE-SW-oriented structures were inactivated, may result from their passive behavior favored by the lack of sedimentary cover, that in turns is the result of bottom currents activity sweeping the study area, producing the erosion/non deposition over diapiric ridges and the development of thick contouritic drifts in the areas between diapirs. Together with sea-level changes, recent tectonic deformation is demonstrated as a key control in the development of contouritic-gravitational systems, and has to be incorporated in the investigation of their reservoir potential.

Acknowledgements

This work has been possible thanks to funding provided by the following projects funded by the Spanish Ministry of Economy and Competitivity: TALUS (CGL2015-74216-JIN), INPULSE (CTM2016-75129-C3-1-R), CONTOURIBER (CTM2008-06399-04-04), MOWER (CTM-2012-395599-C03), SCORE (CGL2016-80445-R; AEI/FEDER, UE), and FAUCES (CTM2015-65461-C2-1-R). We are very grateful to REPSOL for allowing us to use an unpublished seismic line S81A-16 from the Gulf of Cadiz. The investigation has been conducted within the framework of “The Drifters” Research Group (Royal Holloway University of London). We are very grateful to Dr. Vittorio Maselli and Dr. Davide Gamboa for their careful review of the manuscript and the helpful comments and suggestions. We also thank the Associate Editor, Dr. Andrew Green, for his support in the publication process.

1177 Figure Captions

1178 Figure 1. a) Regional bathymetric map of the Gulf of Cadiz contourite depositional system showing the
1179 main MOW cores and branches. ML: Mediterranean Lower core; MU: Mediterranean Upper
1180 core; SB: Southern branch; PB: Principal branch; IB: Intermediate branch; 1: proximal scour and
1181 sand ribbons sector; 2: active contourite drift sector; CC: Contourite channel; SD: Sheeted drift;
1182 GDR: Guadalquivir diapiric ridge; CDR: Cadiz diapiric ridge; b) Datasets used in this work include
1183 the swath bathymetric mosaic and airgun and multichannel seismic lines.

1184 Figure 2. a) Flow distribution of the MOW along the upper and middle slope. Flow direction and
1185 velocity is taken from Sánchez-Leal et al. (2017); CC; Contourite channel; b) Hydrographic
1186 profiles showing the distribution of the East North Antarctic Central Water (ENACW) and the
1187 Mediterranean Outflow Water (MOW) that affect at present day the Cadiz upper and middle
1188 slope (modified from Sánchez-Leal et al., 2017).

1189 Figure 3. a) Bathymetric map of the study area showing the location of the correlated profiles in b) and
1190 c); CC: Contourite Channel (N: Northern; S: Southern; T: Tofiño; G: Gusano; H: Huelva; C: Cadiz);
1191 CDR: Cadiz diapiric ridge; GDR: Guadalquivir diapiric ridge; b) airgun line CADIZ21; c)
1192 multichannel line S81A-16, modified from Hernández-Molina et al. (2014, 2016), from which the
1193 Mid-Pleistocene Discontinuity (MPD) and Late Quaternary Discontinuity (LQD) have been taken.
1194 d) Table showing the links between the seismic units and sub-units from this work with previous
1195 stratigraphic units and discontinuities. The units and sub-units are tentatively correlated with
1196 the climatic record represented by the benthic d18O isotopic curve of Lisiecki and Raymo (2005).

1197 Figure 4. Physiographic characterization of the Gulf of Cadiz continental margin close to the Strait of
1198 Gibraltar. a) Bathymetric map showing the physiographic domains, the location of the study
1199 area and the three major areas (Southern, Central and Northern) considered in this work; b)
1200 Bathymetric profiles from the outer continental shelf down to the proximal middle slope. See
1201 location in a and b).

1202 Figure 5. a) Bathymetry of the continental margin showing the location of the study area and the
1203 bathymetry and profiles shown in Fig.5b to Fig.5e; b) 3D model of the study area showing the
1204 Southern, Central and Northern areas considered in this work; c) Detail of the bathymetric map
1205 showing sediment waves; c) Detail of the bathymetric map showing the sediment waves in the
1206 Northern area; d) shelf-edge escarpment and its bathymetric profile; e) Topographic profiles
1207 across the slope gullies.

1208 Figure 6. a) Map of the basement depth, showing the main features that include two NE-SW-oriented
1209 depressions and small basins. Outcropping diapirs are shown in orange colors, and white dots
1210 represent the top of buried diapirs. This figure shows the two main orientations of these aligned
1211 diapirs, NW-SE and NE-SW; CC: Contourite Channel; CDR: Cadiz diapiric ridge; GDR: Guadalquivir
1212 diapiric ridge; b) Multichannel seismic profiles showing the basement, diapirs and faults in a
1213 downslope direction.

1214 Figure 7. Shallower airgun profiles in orientations parallel to the isobaths and their interpretation. The
1215 seismic units and sub-units and their seismic character is detailed, as well as the features
1216 identified in the profiles (faults, gullies, chaotic-transparent deposits). The alignment of diapir

tops are shown. Orange: NE-SW-oriented diapirs. Blue: NW-SW-oriented diapirs. CDR: Cadiz diapiric ridge; GDR: Guadalquivir diapiric ridge.

Figure 8. Deeper airgun profiles in orientations parallel to the isobaths and their interpretation. The seismic units and sub-units and their seismic character is detailed, as well as the features identified in the profiles (faults, gullies, chaotic-transparent deposits). The alignment of diapir tops are shown. Orange: NE-SW-oriented diapirs. Blue: NW-SW-oriented diapirs. CDR: Cadiz diapiric ridge; GDR: Guadalquivir diapiric ridge.

Figure 9. a) Bathymetric map showing the location of the airgun profiles shown in Fig. 9b, Fig. 10 and Fig. 11 and the position of buried and outcropping diapirs. Orange: NE-SW-oriented diapirs. Blue: NW-SW-oriented diapirs; b) Airgun profile and stratigraphic interpretation orientated perpendicular to the isobaths in the Southern area. The seismic units and sub-units and their seismic character is detailed, as well as the features identified in the profiles. See location and legends in a).

Figure 10. Airgun profile and stratigraphic interpretation orientated perpendicular to the isobaths in the Central area. The seismic units and sub-units and their seismic character is detailed, as well as the features identified in the profiles. The mounded-prograding deposits in sub-unit Q6-c is detailed in the zoomed image. See location and legends in Fig. 9a.

Figure 11. Airgun profile and stratigraphic interpretation orientated perpendicular to the isobaths in the Northern area. The seismic units and sub-units and their seismic character is detailed, as well as the features identified in the profiles. See location and legends in Fig. 9a; HCC: Huelva contourite channel.

Figure 12. Isochore maps highlighting the distribution of depocenters of the two main seismic units and topography of their base (MPD: Mid Pleistocene Discontinuity; LQD; Late Quaternary Discontinuity) and isochore maps of the sub-units depocenters. CDR: Cadiz diapiric ridge; GDR: Guadalquivir diapiric ridge. The present-day location of the shelf break (discontinuous dark blue line) and main contourite channels (CC, in pink) along the middle slope is included as a reference.

Figure 13. Sketches of the diapiric activity, bottom current distribution and sedimentary processes along the two stages of evolution of the Gulf of Cadiz continental margin in the area close to the Strait of Gibraltar: a) Mid Pleistocene Discontinuity to Late Quaternary Discontinuity; b) Late Quaternary Discontinuity to Present. The base topography of the base of unit Q5 (MPD) and Q6 (LQD) are shown for reference.

The role of late Quaternary tectonic activity and sea-level changes on sedimentary processes interaction in the Gulf of Cadiz upper and middle continental slope (SW Iberia)

García, M., Llave, E., Hernández-Molina, F.J., Lobo, F.J., Ercilla, G., Alonso, B., Casas, D., Mena, A., Fernández-Salas, L.M.

Highlights

- We show diapiric activity and sea-level control on sedimentation in the Gulf of Cadiz
- A plastered drift was deposited during lowstands on the ENACW-affected upper slope
- A contourite channel was incised in the proximal middle slope by the MOW
- Since the Late Quaternary diapiric activity changed its trend and migrated to the NW
- Sedimentary processes adapted to the margin morphology created by diapir activity

Declaration of interests
