Theory of Andreev Bound States in S-F-S Junctions and S-F Proximity Devices

M. Eschrig

Andreev bound states are an expression of quantum coherence between particles and holes in hybrid structures composed of superconducting and non-superconducting metallic parts. Their spectrum carries important information on the nature of the pairing, and determines the current in Josephson devices. Here I focus on Andreev bound states in systems involving superconductors and ferromagnets with strong spin-polarization. I provide a general framework for non-local Andreev phenomena in such structures in terms of coherence functions, and show how the latter link wave-function and Green-function based theories.

1. Andreev reflection phenomena

In an isotropic non-magnetic superconductor the normal-state single-particle excitation spectrum $\varepsilon_k$ is modified in the superconducting state to $E_k = [(\varepsilon_k - \mu)^2 + \Delta^2]^{1/2}$, acquiring a gap $\Delta$ around the electrochemical potential $\mu$, and the density of states is characterized by a coherence peak just above the gap, accounting for the missing sub-gap states. This spectral signature, predicted by Bardeen-Cooper-Schrieffer (BCS) theory [1,2] has been first observed by infrared absorption spectroscopy [3,4] and by tunneling spectroscopy [5].

The spectral features above the gap may show information about electron-phonon interaction (or about interaction with some low-energy bosonic modes, e.g. spin-fluctuations [6]), or may exhibit geometric interference patterns. Features due to electron-phonon interaction, predicted by Migdal-Eliashberg theory [7, 8] and studied in detail by Scalapino et al. [9], were measured early in tunneling experiments by Giaever et al. [10]. They are a consequence of electronic particle-hole coherence in a superconductor and build the basis for the McMillan-Rowell inversion procedure for determining the Eliashberg effective interaction spectrum $\alpha^2 F(\omega)$ [11]. Geometric interference effects include oscillations.

in the density of states, such as Tomash oscillations in N-I-S and N-I-S-N' tunnel structures with a superconductor of thickness \(d_N\) (and with transverse Fermi velocity \(v_{F,x}\)), giving rise to voltage peaks at \(eV_n = [(2\Delta)^2 + (n\pi\hbar v_{F,y}/d_N)^2]^{1/2}\) \((n\text{ integer})\) [12–14]; and Rowell-McMillan oscillations in N-I-N'-S tunnel structures with a normal metal \(N'\) of thickness \(d_{N'}\) (transverse Fermi velocity \(v_{F,N'}\)), giving rise to voltage peaks at \(eV_n = n\pi\hbar v_{F,N'}/2d_{N'}\) [15]. Possible offsets due to spatial variation of the gap \(\Delta\) may occur [16].

Inhomogeneous superconducting states exhibit also features at energies inside the gap. Surface bound states in a normal metal overlayer on a superconductor were predicted first by de Gennes and Saint-James [17,18] and measured by Rowell [19] and Bellanger et al. [20]. These de Gennes-Saint-James bound states have a natural explanation in terms of the so-called Andreev reflection process, an extremely fruitful physical picture suggested in 1964 by Andreev [21]. For example, geometric resonances above the gap appear due to Andreev reflection at N-S interfaces, which describe (for normal impact) scattering of a particle at wavevector \(k_{F,x}\) into a hole at wavevector \(k_{F,x} - (E^2 - \Delta^2)^{1/2}/\hbar v_{F,x}\) or vica versa. Below the gap Andreev reflections lead to subharmonic gap structure due to multiple Andreev reflections at voltages \(V_n = 2\Delta/en\) \((n\text{ integer})\) in SIS junctions [22] (for a general treatment in diffusive systems see [23]), and control electrical and thermal resistance of a superconductor/normal-metal interface and the Josephson current in a superconductor/normal-metal/superconductor junction. The Andreev mechanism also gives rise to bound states in various systems with inhomogeneous superconducting order parameter, which are named in the general case Andreev bound states.

Transport trough an N-S contact is strongly influenced by Andreev scattering, and is described in the single-channel case by the theory of Blonder, Tinkham, and Klappwijk [24], generalized to the multi-channel case by Beenakker [25]. Andreev scattering at N-S interfaces is the cause of the superconducting proximity effect [26,27]. Interference effects in transport appear also as the result of impurity disorder. In contrast to unconventional superconductors, where normal impurities are pair breaking, isotropic \(s\)-wave superconductors are insensitive to scattering from normal impurities for not too high impurity concentration, which is the content of a theorem by Abrikosov and Gor’kov [28,29], and by Anderson [30]. In strongly disordered superconductors (weak localization regime) the superconducting transition temperature \(T_c\) is reduced [31], accompanied by localized tail states (similar to Lifshitz tail states in semiconductors [32]) just below the gap edge [33,34]. An interference effect is the so-called reflectionless tunneling [25,35–38], which leads to a zero-bias conductance peak in a diffusive N-I-S structure. It results from multiple scattering of Andreev-reflected coherent particle-hole pairs at impurities, and from the resulting backscattering to the interface barrier, making the barrier effectively transparent near the electrochemical potential for a pair current even in the tunneling regime.

Abrikosov and Gor’kov developed in 1960 a theory for pair-breaking by paramagnetic impurities, showing that at a critical value for the impurity concentration superconductivity is destroyed, and that gapless superconductivity can exist in a narrow region below this critical value [39]. Yu [40], Shiba [41], and Rusinov [42] (who happened to work isolated from each other in China, Japan, and Russia) independently discovered within the framework of a full \(t\)-matrix treatment of the problem that local Andreev bound states (now called the Yu-Shiba-Rusinov states) are present within the BCS energy gap due to multiple scattering between conduction electrons and paramagnetic impurities. Andreev bound states also exist in the cores of vortices in type II superconductors. These are called Caroli-de Gennes-Matricon bound states [43], and carry current in the core region of a vortex [44]. Their dynamics plays a crucial role in the absorption of electromagnetic waves [45–47].

In an S-N-I or S-N-S junction, Andreev bound states appear in the normal metal region at energies below the gaps of the superconductors. The number and distribution of these bound states depend on details such as interface transmission, mean free path, and length of the normal metal \(d_N\). In general, there is a characteristic energy, the Thouless energy [46] (related to the dwell time between Andreev reflections), given by \(\hbar v_{F,N}/D_N\) for the clean limit, and by \(\hbar D_N/d_N^2\) for the diffusive limit, with Fermi velocity \(v_{F,N}\) and diffusion constant \(D_N\) of the normal metal.
In the diffusive limit, the Andreev states build a quasi-continuum below the superconducting gap, whereas in the case of ballistic junctions bands of Andreev bound states arise. For the case that no superconducting phase gradient (and no paramagnetic pair breaking) is present in the system, however, a low-energy gap always arises in the spectrum of Andreev states in the normal metal. This so-called minigap scales for sufficiently thick normal metal layers approximately with its Thouless energy and with the transmission probability (possibly further reduced by inelastic scattering processes). It was found first by McMillan [49] and can be probed by scanning tunneling microscopy [50]. In chaotic Andreev billiards [51], where disorder is restricted to boundaries, a second time scale, the Ehrenfest time, competes with the dwell time to set the minigap [52].

The importance of Andreev bound states in S-N-S Josephson junctions for current transport was first discussed by Kulik in 1969 [33]. Andreev bound states form in a sufficiently long normal region, which are doubly degenerate (carrying current in opposite direction) for zero phase difference between the superconducting banks. For a finite phase difference, this degeneracy is lifted. The gap or minigap in a Josephson structure is reduced and eventually closes when a region, which are doubly degenerate (carrying current in opposite direction) for zero phase was first discussed by Kulik in 1969 [53]. Andreev bound states form in a sufficiently long normal metal. This so-called minigap scales for sufficiently thick normal metal layers approximately with its Thouless energy and with the transmission probability (possibly further reduced by inelastic scattering processes). It was found first by McMillan [49] and can be probed by scanning tunneling microscopy [50]. In chaotic Andreev billiards [51], where disorder is restricted to boundaries, a second time scale, the Ehrenfest time, competes with the dwell time to set the minigap [52].

The importance of Andreev bound states in S-N-S Josephson junctions for current transport was first discussed by Kulik in 1969 [33]. Andreev bound states form in a sufficiently long normal region, which are doubly degenerate (carrying current in opposite direction) for zero phase difference between the superconducting banks. For a finite phase difference, this degeneracy is lifted. The gap or minigap in a Josephson structure is reduced and eventually closes when a supercurrent flows across the junction. This is a result of a “dispersion” of the energy $E_{b,s}$ of the Andreev bound states as function of phase difference $\Delta \chi$ between the superconducting banks [53–55]. The contribution of the bound states to the supercurrent is given by $\partial E_{b,s}/\partial \Delta \chi$, with $e < 0$ the electron charge. Apart from the current carried by the Andreev bound states, there is also a contribution from continuum states above the gap [53]. For a single-channel weak link between two superconductors with normal-state transmission probability $\tau$, there is one pair of Andreev bound states with dispersion $E_{\pm} = \pm \Delta [1 - \tau^2 \sin^2(\Delta \chi/2)]^{1/2}$.

The large size of a Cooper pair in conventional superconductors leads to a pronounced non-locality of Andreev reflection processes. This allows for interference effects due to crossed Andreev reflection, in which the particle and hole involved in the process enter different normal-state (typically spin-polarized) terminals, which are both simultaneously accessible to one Cooper pair [56,57]. This effect has been first experimentally observed by Beckmann et al. [58].

Finally, an important role is played by Andreev zero modes as topological surface states. Examples are zero-bias states at the surface of a $d$-wave superconductor [59,60], and Majorana zero modes in topological superconductors [61,62] and superfluids [63].

2. Andreev bound states at magnetically active interfaces

(a) Spin-dependent interface scattering phase shifts

The importance of spin-dependent interface scattering phase shifts for superconducting phenomena has been pioneered in the work of Tokuyasu, Sauls, and Rainer in 1988 [64]. Consider an interface between a normal metal (N) at $x < 0$ and a ferromagnetic insulator (FI) or a half-metallic ferromagnet (HM) at $x > 0$. For simplicity, let us model the FI (or HM) by a single electronic band with energy gap $V_\uparrow$, for spin-down particles and an energy gap $V_\downarrow = V_\uparrow - 2J$ for spin-up particles, where $J > 0$ denotes an effective exchange field. The exchange field can be related to an effective magnetic field via $\mu_B \text{eff} = J$ (for free electrons the magnetic moment is $\mu = \mu_c < 0$). Let us assume an incoming Bloch electron with energy $0 < E < V_\uparrow$ and spin $\sigma \in \{\uparrow, \downarrow\}$, reflected back from the interface with amplitude $r_\sigma$. It is described by a wave function $\psi_\sigma(x, r_\uparrow) = e^{ik_\downarrow r_\downarrow} e^{ik_\uparrow r_\uparrow} e^{-ik_\downarrow x}$ at $x < 0$ and $\psi_\sigma(x, r_\uparrow) = t_\sigma e^{ik_\downarrow r_\downarrow} e^{-ik_\uparrow x}$ at $x > 0$. For the normal metal $\hbar k(E) = [2mE - (\hbar k_\|)^2]^{1/2}$. For the FI $\hbar k_\sigma(E) = [2m(V_\sigma - E) + (\hbar k_\|)^2]^{1/2}$.

The reflection scattering matrix is

$$S = \begin{pmatrix} e^{i\theta_\uparrow} & 0 \\ 0 & e^{i\theta_\downarrow} \end{pmatrix}, \quad e^{i\theta_\uparrow} = r_\uparrow = \frac{k - ik_\uparrow}{k + ik_\uparrow}, \quad e^{i\theta_\downarrow} = r_\downarrow = \frac{k - ik_\downarrow}{k + ik_\downarrow} \quad (2.1)$$

In the range $V_\downarrow < E < V_\uparrow$ the spin-up electron can be transmitted for sufficiently small $k_\|$ with amplitude $t_\uparrow = 2\sqrt{\hbar k_\|(k + k_\uparrow)}$, where $\hbar k_\uparrow(E) = [2m(E - V_\uparrow) - (\hbar k_\|)^2]^{1/2}$. In this case, the reflection amplitude is also real, and equal to $r_\uparrow = (k - k_\uparrow)/(k + k_\uparrow)$. The reflection phase is $-\pi$
Figure 1. Spin dependent scattering phase shifts for Bloch waves with energy $E_F$ reflected from an N-FI or N-HM interface (at $x = 0$). Here $V_\downarrow = 3E_F$ is fixed and $V_\uparrow$ varied from $-E_F$ to $3E_F$ (i.e. the parameter $(V_\uparrow - E_F)/E_F$ is varied from $-2$ to $2$), $k_\parallel = 0$. For $V_\uparrow > E_F$ this describes a FI, for $V_\uparrow < E_F$ a HM. For $V_\uparrow < 0$ the Fermi surface of the spin-up band in the HM becomes larger than in N. Shown are for $x<0$ the (normalized) reflected wave, quantified by $-\text{Im}(r_\uparrow e^{-ik_\parallel x})/|r_\uparrow|$, and for $x>0$ the transmitted wave, quantified by $-\text{Im}(t_\uparrow e^{ik_\parallel x})$ (for real $k_\uparrow$) or $-\text{Im}(t_\uparrow e^{ik_\parallel x})$ (for real $k_\downarrow$, i.e. $V_\uparrow < E_F$). The spin-up wave is shown in orange, the spin-down wave in blue.

for $k < k_\uparrow$ and zero for $k > k_\uparrow$. In figure 1, $V_\downarrow = 3E_F$ is fixed and $V_\uparrow$ varied from $-E_F$ to $3E_F$, $k_\parallel = 0$. A phase shift for reflected waves between the two spin projections appears.

It results from the well-known effect that reflection from an insulating region results in a phase-delay of the reflected wave with respect to the case of an infinite interface potential. This phase delay appears due to the quantum mechanical penetration of the wave function into the classically forbidden region. The range $V_\uparrow - E_F > 0$ in figure 1 corresponds to an N-FI interface, where both spin-projections are evanescent in FI. Here, the reflected spin-up wave trails that of the spin-down wave, and the effect increases when $V_\uparrow - E_F$ approaches zero. The phase $\vartheta = \vartheta_\uparrow - \vartheta_\downarrow$ of the parameter $r_\uparrow^* r_\downarrow = |r_\uparrow r_\downarrow| e^{i\vartheta}$ is called spin-mixing angle [64], or spin-dependent scattering phase shift [65]. It is an important parameter for superconducting spintronics. For the N-FI model interface it is given by

$$
\tan \frac{\vartheta}{2} = \tan \frac{\vartheta_\uparrow - \vartheta_\downarrow}{2} = \frac{k(k_\downarrow - k_\uparrow)}{k^2 + \kappa_\uparrow \kappa_\downarrow},
$$

(2.2)

which is positive due to $k_\downarrow > k_\uparrow$. The range $V_\uparrow - E_F < 0$ corresponds to a N-HM interface, with the spin-up band itinerant in HM. Here, as long as the spin-up Fermi wavevector in the HM is smaller than that in N (for $-1 < (V_\uparrow - E_F)/E_F < 0$), the reflection phase in $r_\uparrow$ is zero, and

$$
\tan \frac{\vartheta}{2} = \tan \frac{-\vartheta_\downarrow}{2} = \frac{\kappa_\downarrow}{k},
$$

(2.3)

which can acquire large values. Finally, in the range $(V_\uparrow - E_F)/E_F < -1$ the Fermi wavevector in the HM is larger than in N, which leads to a reflection phase of $\pi$ for spin-up particles, and

$$
\tan \frac{\vartheta}{2} = \tan \frac{\pi - \vartheta_\downarrow}{2} = \frac{k}{\kappa_\downarrow},
$$

(2.4)

which now is negative.

In ballistic structures, the spin-mixing angle depends on the momentum $\hbar k_\parallel$ parallel to the interface, as illustrated in figure 2 for varying Fermi surface geometry in the ferromagnet, here
parameterized by varying \((V_{↑} + V_{↓})/2\) keeping \(J\) fixed. If both spin-bands are itinerant in the ferromagnet (F), then the spin-mixing angle is either zero (if \(k > k_{↑}, k_{↓}\) or \(k < k_{↑}, k_{↓}\), cyan area in figure 2 (a)) or \(-\pi\) (if \(k_{↑} > k > k_{↓}\), red areas in figure 2), unless an interface potential exists, rendering the reflection amplitudes complex valued. In general, the spin-mixing angle should be considered as material parameter, which in addition depends on the impact angle of the incoming electron or on transport channel indices.

Note that the parameter \(r_{↑}r_{↓}^{\ast}\) has become well-known in the spintronics community, as it governs the spin mixing conductance [66] in spintronic devices.

It is also instructive to study an incoming Bloch-electron polarized in a direction different from the magnetization direction in the ferromagnet. Let us consider the case of a FI. For a Bloch electron polarized in a direction \(n(\alpha, \phi)\), parameterized by polar and azimuthal angles, \(\alpha\) and \(\phi\),

\[
\uparrow_{\alpha, \phi} e^{i k_{↑} r_{x}} e^{i k_{x}} = \left[ \cos \frac{\alpha}{2} e^{-i \frac{\phi}{2}} + \sin \frac{\alpha}{2} e^{i \frac{\phi}{2}} \right] e^{i k_{↑} r_{x}} e^{i k_{x}}
\]

the reflected wave will have the form

\[
\left[ \cos \frac{\alpha}{2} e^{-i \frac{\phi}{2}} - \sin \frac{\alpha}{2} e^{i \frac{\phi}{2}} \right] \left[ \cos \frac{\alpha}{2} e^{-i \frac{\phi}{2}} + \sin \frac{\alpha}{2} e^{i \frac{\phi}{2}} \right] e^{i k_{↑} r_{x}} e^{-i k_{x}} \equiv \uparrow_{\alpha, \phi - \vartheta} e^{i \vartheta} e^{i k_{↑} r_{x}} e^{-i k_{x}}
\]

with \(\vartheta = (\vartheta_{↑} + \vartheta_{↓})/2\). Similarly, \(\downarrow_{\alpha, \phi}\) scatters into \(\downarrow_{\alpha, \phi - \vartheta} e^{i \vartheta}\). This means that scattering leads, apart from an unimportant spin-independent phase factor \(e^{i \vartheta}\), to a precession of the spin around the magnetization axis [64]. The direction of precession depends on the Fermi surface geometries, and is determined by the sign of the spin-mixing angle \(\vartheta\).

The discussion above is generic and is easily generalized to anisotropic Fermi surfaces, Fermi velocities, and effective exchange fields. The central quantity of the theory is the scattering matrix \(S\), the eigenvalues of which are given for conserved \(k_{∥}\) by \(e^{i \vartheta_{↑}(k_{||})}\) and \(e^{i \vartheta_{↓}(k_{||})}\), and the eigenvectors of which determine for each \(k_{∥}\) the quantization axis along which the scattering matrix is diagonal, and around which the spin precession takes place.

(b) Andreev reflection in an S-N-FI structure

An important consequence of spin-mixing phases is the appearance of Andreev bound states at magnetically active interfaces, predicted theoretically [67-73], and verified experimentally [74].

Consider a superconductor near an interface with a ferromagnetic insulator. Let us assume that the superconducting order parameter is suppressed to zero in a layer of thickness \(d\) next to the FI interface, such that the structure can be described as an S-N-FI junction with identical normal state parameters in S and N. For simplicity I consider here a spatially constant order parameter in

Figure 2. Spin mixing angle \(\vartheta\) as function of parallel momentum \(k_{∥}/k_{F}\) and \(\nu = (V_{↑} + V_{↓})/2\); (a): for effective exchange field \(J = 0.3 E_{F}\) (FI for \(\nu > 1.3\), HM for \(\nu > 0.7\); (b): for \(J = 0.8 E_{F}\) (FI for \(\nu > 1.8\), HM for \(\nu > 0.2\).
S (extending to the half space \( x < 0 \)). The FI \((x > d)\) will be parameterized by reflection phases \( \vartheta_{\uparrow} \) and \( \vartheta_{\downarrow} \), with spin-mixing angle \( \vartheta = \vartheta_{\uparrow} - \vartheta_{\downarrow} \). Solving the corresponding Bogoliubov-de Gennes equations in the superconductor \((\sigma_0 \text{ are spin Pauli matrices, } \sigma_0 \text{ a } 2 \times 2 \text{ unit spin matrix})\)

\[
\begin{pmatrix}
-\frac{\hbar^2 \nabla^2}{2m} - \mu \\
-\Delta^2 & \mu
\end{pmatrix}
\begin{pmatrix}
u \\
v
\end{pmatrix}
= \varepsilon
\begin{pmatrix}
u \\
v
\end{pmatrix}
\]

(2.7)

with spinors \( u \) and \( v \), the (still unnormalized) eigenvectors for given energy \( \varepsilon \) and \( k_{||} = 0 \) are

\[
\begin{pmatrix}
1 \\
0 \\
\gamma
\end{pmatrix} e^{\pm i k_x x}, \begin{pmatrix}
0 \\
1 \\
-\gamma
\end{pmatrix} e^{\pm i k_y y}, \begin{pmatrix}
0 \\
1 \\
0
\end{pmatrix} e^{\pm i k_z z}, \begin{pmatrix}
0 \\
0 \\
1
\end{pmatrix} e^{\pm i k_r r}
\]

(2.8)

where to first order in \(|\Delta|/E_F \) the wavevectors are \( k_{\pm}(\varepsilon) = k_F \pm i/2 \frac{\Delta}{\varepsilon - E_F} \) and

\[
\gamma(\varepsilon) = -\frac{\Delta}{\varepsilon + 1/2 \frac{\Delta^2}{\varepsilon - E_F}}, \quad \tilde{\gamma}(\varepsilon) = \frac{\Delta^*}{\varepsilon + 1/2 \frac{\Delta^2}{\varepsilon - E_F}}.
\]

(2.9)

For \(|\varepsilon| > |\Delta| \) the expression \( i/2 \frac{\sqrt{|\Delta|^2 - \varepsilon^2}}{\varepsilon - E_F} \) is replaced by \( \varepsilon \sqrt{1 - (|\Delta|/|\varepsilon|)^2} \) (which corresponds to \( \varepsilon \to \varepsilon + i \delta^+ \) with infinitesimally small positive \( \delta^+ \)). In the N layer the solutions are obtained by setting \( \Delta = 0 \). In the FI only evanescent solutions of the form \( e^{-\gamma/E_F} \) and \( e^{-\gamma/E_F} \) are allowed. The reflection coefficients connect incoming \((e^{i k_+}, e^{-i k_+}) \) solutions with outgoing \((e^{-i k_+}, e^{i k_+}) \) solutions. For scattering from electron-like to electron-like Bogoliubov quasiparticles and for electron-like to hole-like Bogoliubov quasiparticles in leading order in \(|\Delta|/E_F \) they are

\[
r_{e\uparrow\rightarrow e\uparrow} = \frac{e^{2 i k_F} e^{2 i d / r} e^{-i \vartheta} (1 + \gamma \tilde{\gamma})}{1 + \gamma \tilde{\gamma} e^{-2 i d / r} e^{i \vartheta}}, \quad r_{e\uparrow\rightarrow h\downarrow} = -\frac{\gamma (1 - e^{2 i d / r} e^{i \vartheta})}{1 + \gamma e^{2 i d / r} e^{i \vartheta}},
\]

\[
r_{h\uparrow\rightarrow h\uparrow} = \frac{e^{-2 i k_F} e^{-2 i d / r} e^{-i \vartheta} (1 + \gamma \tilde{\gamma})}{1 + \gamma \tilde{\gamma} e^{-2 i d / r} e^{-i \vartheta}}, \quad r_{h\uparrow\rightarrow e\downarrow} = -\frac{\gamma (1 - e^{-2 i d / r} e^{-i \vartheta})}{1 + \gamma e^{-2 i d / r} e^{-i \vartheta}}.
\]

(2.10)

(2.11)

and similar relations hold for \( \uparrow\downarrow \) and simultaneously \( \vartheta \to -\vartheta, \gamma \to -\gamma, \tilde{\gamma} \to -\tilde{\gamma} \). These relations have a simple interpretation. The coherence functions \( \gamma \) and \( \tilde{\gamma} \) represent probability amplitudes for hole-to-particle conversion \((\gamma)\) or particle-to-hole conversion \((\tilde{\gamma})\), whereas the factors \( e^{\pm i d / r} \) represent the electron-hole dephasing when crossing the N layer. Thus, the factors \( \gamma \tilde{\gamma} e^{2 i d / r} e^{-i \vartheta} \) represent a Rowell-McMillan process of four times crossing N with two reflections from FI (once as particle and once as hole, contributing \( e^{i \vartheta} \) and \( e^{-i \vartheta} \)), and two Andreev conversions. When this factor equals\(-1\), which happens for energies below the gap, a bound state appears in \( N \) due to constructive interference between particles and holes. Note that for \( |\varepsilon| \lesssim |\Delta| \) the coherence functions have unit modulus: \(|\gamma| = |\tilde{\gamma}| = 1\), such that with \( \Delta = |\Delta| e^{i \chi} \) one can write \( \gamma = e^{i \vartheta} e^{i \chi} \) and \( \tilde{\gamma} = -e^{i \vartheta} e^{-i \chi} \), with sin \( \vartheta = \varepsilon/|\Delta| \), cos \( \vartheta > 0 \). For \(|\varepsilon| < |\Delta| \) only outgoing wavevectors \(-k_+ \) and \( k_- \) lead to normalizable solutions in the superconductor, which are restricted to the bound state energies, given by the solution of \( \varepsilon = |\Delta| \sin(2 \Delta k_F / \hbar) \).
Figure 3. Imaginary part of Andreev reflection amplitudes for spin-up Bogoliubov quasiparticle to spin-down Bogoliubov quasihole, $\text{Im}(r_{e\uparrow \rightarrow h\downarrow})$, at normal impact, for an S-N-FI structure with a normal region of thickness $d$, as function of energy $\varepsilon$, and of $d$ (in units of $\xi_0 = \hbar v_{F,z}/\Delta$ with $v_{F,z}$ the projection of the Fermi velocity on the surface normal). The reflection amplitude at the N-FI interface is for spin-up $e^{i\vartheta\uparrow}$ and for spin-down $e^{i\vartheta\downarrow}$. The spin-mixing angle is defined as $\vartheta = \vartheta\uparrow - \vartheta\downarrow$. It has the values (a) $\vartheta = 0$, (b) $\vartheta = \pi/2$, (c) $\vartheta = \pi$. In (d)-(f) the thickness of the normal layer is fixed to (d) $d = 0$, (e) $d = \xi_0$, (f) $d = 2\xi_0$, and the spin-mixing angle $\vartheta$ varied. The negative reflection amplitude for spin-down quasiparticle to spin-up quasihole, $-\text{Im}(r_{e\downarrow \rightarrow h\uparrow})$, is obtained by inverting the energy axis, $\varepsilon \leftrightarrow -\varepsilon$.

one needs a variation exceeding $2\pi$ (up to multiple times) until the branch crosses the entire gap. The figure shows results for normal impact, $k_\parallel = 0$. In general, an integration over $k_\parallel$ will lead to Andreev bands instead of sharp bound states, similar as in the case of de Gennes-Saint-James bound states in S-N-I structures.

Finally, note that with the reflection matrix (2.1) the resulting coherence function develops a spin-triplet component from a singlet component $\gamma_{10} = \gamma_{03}\sigma_2$:

\[
\begin{pmatrix}
0 & \gamma_{\text{out}\downarrow\uparrow} \\
\gamma_{\text{out}\uparrow\downarrow} & 0
\end{pmatrix} =
\begin{pmatrix}
e^{i\vartheta\uparrow} & 0 \\
0 & e^{i\vartheta\downarrow}
\end{pmatrix}
\begin{pmatrix}
0 & \gamma_0 \\
-\gamma_0 & 0
\end{pmatrix}
\begin{pmatrix}
e^{-i\vartheta\uparrow} & 0 \\
0 & e^{-i\vartheta\downarrow}
\end{pmatrix}
= \cos(\vartheta)
\begin{pmatrix}
0 & \gamma_0 \\
-\gamma_0 & 0
\end{pmatrix} + i\sin(\vartheta)
\begin{pmatrix}
0 & \gamma_0 \\
\gamma_0 & 0
\end{pmatrix}
\]

(2.12)

which implies that a singlet pair is scattered into a superposition of a singlet and a triplet pair:

\[
(\uparrow\downarrow \rightarrow (\uparrow\downarrow e^{i\vartheta\uparrow} - \downarrow\uparrow e^{-i\vartheta\downarrow}) = \cos(\vartheta)(\uparrow\downarrow) + i\sin(\vartheta)(\downarrow\uparrow + \uparrow\downarrow).
\]

(2.13)

(c) Andreev bound states in an S-FI-N structure

As the next example I summarize some results from Refs. [75,76] and section IV of Ref. [78] for an S-FI-N junction, consisting of a bulk superconductor coupled via a thin ferromagnetic insulator (such as EuO) of thickness $d_I$ to a normal layer of thickness $d_N$. I assume here the ballistic case,
and refer for the diffusive case to Refs. [75–77]. The interface is characterized by potentials \( V_\parallel \) and \( V_\perp = V_\parallel + 2J \), such that the energy dispersion in the superconductor is \( \hbar^2 k^2/2m \), in the normal metal \( V_N + \hbar^2 k^2/2m \), and in the barrier \( V_B + \hbar^2 k^2/2m \), \( \sigma \in \{ \uparrow, \downarrow \} \). The parameter \( V_N \) is used to vary the Fermi surface mismatch. We note here in passing that having different effective masses on the two sides of the interface does not introduce new physics: any kinetic energy term of the form \( -\hbar^2 a \partial_x m - \hbar^2 b \partial_x m - c + \hbar c \) with spatially varying \( m \equiv m(x) \) and with \( a + b + c = 1 \) transforms with the substitution \( \Phi(x) \to \sqrt{m(x)} \Phi(x) \) into a potential energy term of the form \( \hbar^2 / 8m \{ 4(1-a)(1-c) - (m^{-1} \partial_x m)^2 - 2bm^{-1} \partial_x^2 m \} \). Thus, the effect on the scattering problem is essentially to renormalize the interface potential and to introduce a Fermi surface mismatch. The Fermi wave vectors and Fermi velocities in S and N are denoted \( k_{FS} \), \( v_{FS} \), and \( k_{FN} \), \( v_{FN} \), respectively. The Fermi energy is \( E_F = \hbar^2 k_{FS}^2 / 2m \). For shorter notation let us introduce a directional vector for electrons moving in positive \( x \)-direction, \( v_{FN} = \{ v_{FN, \uparrow}, v_{FN, \downarrow} \} \) (i.e. \( n_x \geq 0 \)) and the corresponding \( x \)-component of the Fermi velocity, \( v_{FN,x} \equiv v_F \geq 0 \), in the normal metal (situated at \( 0 \leq x \leq d_N \)). It is convenient to define coherence functions \( \gamma \) and \( \tilde{\gamma} \) as \( 2 \times 2 \) spin matrices. The coherence functions in the superconductor are given by \( \gamma = \gamma_0 \theta_2 \) and \( \tilde{\gamma} = \gamma_0 \theta_2 \), where \( \gamma_0 \) and \( \tilde{\gamma}_0 \) are given by the expressions in (2.9). The solutions in the normal metal are (for simplicity of notation I also suppress the arguments \( k_\parallel \) and \( \varepsilon \) in \( \gamma \) and \( \tilde{\gamma} \))

\[
\gamma(n_x, x) = \gamma(n_x, 0)e^{2i\varepsilon(x-n_0)/h v_x}, \quad \gamma(-n_x, x) = \gamma(-n_x, d_N)e^{-2i\varepsilon(x-d_0)/h v_x} \tag{2.14}
\]

\[
\tilde{\gamma}(n_x, x) = \tilde{\gamma}(n_x, 0)e^{2i\varepsilon(x-n_0)/h v_x}, \quad \tilde{\gamma}(-n_x, x) = \tilde{\gamma}(n_x, d_N)e^{-2i\varepsilon(x-d_0)/h v_x} \tag{2.15}
\]

At \( x = d_N \) one obtains \( \gamma(n_x, d_N) = \gamma(-n_x, d_N) \equiv \gamma_B \) and \( \tilde{\gamma}(n_x, d_N) = \tilde{\gamma}(-n_x, d_N) \equiv \tilde{\gamma}_B \), with

\[
\gamma_B = \begin{pmatrix} 0 & \gamma_+ \\ -\gamma_- & 0 \end{pmatrix}, \quad \tilde{\gamma}_B = \begin{pmatrix} 0 & \tilde{\gamma}_+ \\ -\tilde{\gamma}_- & 0 \end{pmatrix}. \tag{2.16}
\]

The scattering parameters are the modulus of the transmission amplitudes, \( t_\parallel \) and \( t_\perp \), the modulus of the reflection amplitudes \( r_\parallel = (1 - t_\parallel^2)^{1/2} \) and \( r_\perp = (1 - t_\perp^2)^{1/2} \) (equal on both sides of the FI), as well as the phase factors of the scattering parameters (all these parameters depend on \( k_\parallel \)). The relevant energy scale in the normal metal for given direction \( n_\parallel \) is

\[
\delta(k_\parallel) = t_\parallel(k_\parallel) t_\perp(k_\parallel) n_x(k_\parallel) \varepsilon_{Th}, \quad \varepsilon_{Th} = \hbar v_{FN} / 2d_N, \tag{2.17}
\]

with the Thouless energy \( \varepsilon_{Th} \). Matching the wavefunctions at \( x = 0 \) to the thin FI layer and the superconductor, leads to \( \gamma_- = -\gamma_+ \) and \( \tilde{\gamma}_- = -\tilde{\gamma}_+ \), as well as [75,76]

\[
\gamma_\sigma = -\frac{\nu_\sigma + 1}{\nu_\sigma + i \sqrt{\delta^2 - (\nu_\sigma + 10)^2}} \tag{2.18}
\]

where \( \sigma \in \{ +, - \} \), and the function \( \nu_\sigma(\varepsilon) \) is defined as

\[
\nu_\sigma(\varepsilon) = n_x \varepsilon_{Th} \left[ \sin \left( \frac{\varepsilon}{n_x \varepsilon_{Th}} + \sigma \partial_+ + \Psi \right) + r_\parallel r_\perp \sin \left( \frac{\varepsilon}{n_x \varepsilon_{Th}} + \sigma \partial_- + \Psi \right) \right] \tag{2.19}
\]

with \( \partial_\pm = \frac{1}{2}(\partial_N \pm \partial_S) \), where \( \partial_N \) and \( \partial_S \) are the spin-mixing angles for reflection at the FI-N interface and the S-FI interface, respectively, and the variable \( \sigma \) is to be understood as a factor \( \pm 1 \) for \( \sigma = \pm \). Note that (2.18) has the same form as (2.9) with the role of \( \Delta \) and \( \varepsilon \) taken over by \( \delta \) and \( \nu_\sigma \), respectively. Note also that \( |\gamma_\sigma| = 1 \) for \( \nu_\sigma < \delta \), even in the tunneling limit. This is an example of reflectionless tunneling at low energies and results from multiple reflections within the normal layer. Quasiparticles in the normal layer stay fully coherent in this energy range.

The density of states at the outer surface of the N layer is obtained as

\[
\frac{N_B(\varepsilon)}{N_{F,N}} = \Re \sum_\sigma \left( 1 + \frac{\gamma_\sigma^2}{1 - \gamma_\sigma^2} \right) = \Re \sum_\sigma \left( \frac{|\nu_\sigma(\varepsilon)|}{\sqrt{|\nu_\sigma(\varepsilon)|^2 - \delta^2}} \right) \tag{2.20}
\]

where \( \langle \ldots \rangle \) denotes Fermi surface averaging, and \( N_{F,N} \) is the density of states at the Fermi level of the bulk normal metal. Results for this density of states are shown in figure 4. The various panels
(a)-(c) show examples for various Fermi surface mismatches. In (c) there are non-transmissive channels present in the normal layer (|k_F| > k_F,S), leading to a large constant background density of states. In each panel, the curve for J = 0 corresponds to the case of a non-spin-polarized SIN junction. There is a critical value J_{crit} (independent of the Fermi surface mismatch and equal to \approx 0.15E_F in the figure) above which the system is in a state where no singlet correlations are present in the normal metal at the chemical potential (\epsilon = 0), and pure odd-frequency spin-triplet correlations remain. In this range the density of states is enhanced above its bulk normal state value [76]. On either side of this critical value the density of states decreases as function of J, however stays always above N_{F,N} for J > J_{crit}. In the diffusive limit a similar scenario arises, with a peak centered at zero energy in the density of states [75,76]. A zero-energy peak in the density of states is enhanced above its bulk normal state value [76]. On either side of this critical value the density of states decreases as function of J, however stays always above N_{F,N} for J > J_{crit}. In the diffusive limit a similar scenario arises, with a peak centered at zero energy in the density of states [75,76]. A zero-energy peak in the density of states has been suggested as a signature of odd-frequency spin-triplet pairing also in hybrid structures with an itinerant ferromagnet or a half-metallic ferromagnet coupled to a superconductor [79–81].

It is interesting to study the tunneling limit, t_\perp \ll 1, t_\parallel \ll 1, for small excitation energies \epsilon \ll \min(\epsilon_{Th}, \Delta) and small spin-mixing angles \theta_N, \theta_S. Then \nu_0 \approx 2\epsilon + \sigma N_\perp \epsilon \Delta \nu N, i.e. \nu_0 depends only on the spin mixing angle at the FI-N interface, which acts in this case as an (anisotropic) effective exchange field b = \bar{n}_N \epsilon_{Th} \nu N / 2 on the quasiparticles. For diffusive structures, a similar connection between an effective exchange field and the spin-mixing angle has been made [82]. The parameter \delta / 2 = t_\perp \sqrt{\bar{n}_N \sigma \epsilon_{Th} / 2} on the other hand acts as effective (anisotropic) gap function. For each direction \bar{n}, the gap closes at a critical value of effective exchange field, b = \delta / 2, which happens for \theta_N = t_\perp t_\parallel.

3. Andreev bound states in Josephson junctions with strongly spin-polarized ferromagnets

(a) Triplet rotation

Interfaces with strongly spin-polarized ferromagnets polarize the superconductor in proximity with it, as shown in the previous section. However, in order for superconducting correlations to penetrate the ferromagnet, it is necessary to turn the triplet correlations of the form \uparrow \downarrow + \downarrow \uparrow into equal spin pair correlations of the form \uparrow \uparrow and \downarrow \downarrow. The reason is that correlations involving spin-up and spin-down electrons involve a phase factor k_F^* - k_F, which in strongly spin-polarized

Figure 4. Energy-resolved DOS in the normal metal for different values of the interface exchange field J. The energy scale is \delta_0 = (t_\perp t_\parallel \epsilon_{Th})_{\epsilon = 0}$, with the Thouless energy \epsilon_{Th} = \hbar v_{F,N} / 2d_N. The interlayer thickness is d_L = 2/k_F,S and the interface potentials are V_\perp = 1.2E_F, V_\parallel = V_\perp + 2J. The width of the normal layer is d_N = \hbar v_{F,N} / \Delta. The inset in the lower left corner of each panel illustrates the Fermi-surface mismatch: in (a) k_{F,N} \approx 0.5k_F,S, in (b) k_{F,N} = k_F,S, and in (c) k_{F,N} = 10k_F,S. Adapted from [76]. Copyright (2010) by the American Physical Society.

(a) Triplet rotation

Interfaces with strongly spin-polarized ferromagnets polarize the superconductor in proximity with it, as shown in the previous section. However, in order for superconducting correlations to penetrate the ferromagnet, it is necessary to turn the triplet correlations of the form \uparrow \downarrow + \downarrow \uparrow into equal spin pair correlations of the form \uparrow \uparrow and \downarrow \downarrow. The reason is that correlations involving spin-up and spin-down electrons involve a phase factor k_F^* - k_F, which in strongly spin-polarized...
ferromagnets oscillates on a short length scale. This leads to destructive interference and allows to neglect such pair correlations on the superconducting coherence length scale [83].

The way to achieve this is to allow for a non-trivial magnetization profile at the interface between the ferromagnet and the superconductor. This can include for example strong spin-orbit coupling, or a misaligned (with respect to the bulk magnetization) magnetic moment in the interface region. For strongly spin-polarized ferromagnets this has been suggested in Ref. [68,84,85]. For weakly spin-polarized ferromagnets a theory was developed in 2001 involving a spiral inhomogeneity on the scale of the superconducting coherence length [86,87]. A multilayer arrangement was subsequently also suggested [88,89]. For various reviews of this field see Refs. [83,90–100].

The idea is to rotate the triplet component, once created by spin-mixing phases in the S-F interfaces, into equal-spin triplet amplitudes with respect to the bulk magnetization of the ferromagnet [97]. This is achieved by writing a triplet component with respect to a new axis

\[
(\uparrow \downarrow + \downarrow \uparrow)_{\alpha,\phi} = -\sin(\alpha) \left[ e^{-i\phi} (\uparrow\uparrow)_z - e^{i\phi} (\downarrow\downarrow)_z \right] + \cos(\alpha) (\uparrow\downarrow + \downarrow\uparrow)_z, \tag{3.1}
\]

where \(\alpha\) and \(\phi\) are polar and azimuthal angles of the new quantization axis. Then, if a thin FI layer oriented along the \((\alpha, \phi)\) direction is inserted between the superconductor and the strongly spin-polarized ferromagnet with magnetization in \(z\) direction, equal spin-correlations can penetrate with amplitudes \(-\sin(\alpha)e^{-i\phi}\) and \(\sin(\alpha)e^{i\phi}\), respectively. These correlations are long-range and not affected by dephasing on the short length scale associated with \(k_F - k_{F_\perp}\).

(b) Pair amplitudes at an S-FI-F interface

It is instructive to consider the scattering matrix of an S-FI-F interface between a superconductor and an itinerant ferromagnet, with a thin FI interlayer of width \(d\), in the tunneling limit. In this case one can achieve an intuitive understanding of the various spin-mixing phases involved in the reflection and transmission processes. Denoting wavevector components perpendicular to the interface as \(k\) in the superconductor, \(q_F\) and \(q_S\) in the ferromagnet (I assume \(k_{\parallel}\) such that both spin directions are itinerant), and imaginary wavevectors \(i\kappa_F\) and \(i\kappa_S\) in the FI, the FI magnetic moment aligned in direction \((\sin \alpha, \cos \alpha, \sin \varphi, \cos \varphi)\), and a F magnetization aligned with the \(z\)-direction in spin space \((\alpha = 0)\), matching of wavefunctions leads to a scattering matrix

\[
S = \begin{pmatrix}
D_\varphi D_\alpha \Phi_S^\dagger & 0 \\
0 & i\bar{D}_\varphi D_\beta \Phi_F^\dagger
\end{pmatrix}
\begin{pmatrix}
\sigma_0 & 2\nu_S T q_{\|} \\
2\nu_F T q_{\|} & -\sigma_0
\end{pmatrix}
\begin{pmatrix}
\Phi_S D_\alpha^\dagger D_\varphi^\dagger & 0 \\
i\Phi_F^\dagger D_\varphi D_\beta^\dagger & 0
\end{pmatrix} \tag{3.2}
\]

where \(\Phi_{S,F}\) are phase matrices which include the spin-mixing phase factors, \(D_\varphi\), \(D_\alpha\), \(D_\beta\) are spin-rotation matrices, \(\nu_{S,F}\) carry information about S-FI and FI-F wavevector mismatch, and \(T\) contains the tunneling amplitudes including wavevector mismatch between S and F. In particular, if one denotes diagonal matrices with diagonal elements \(a, b\) by \(\text{diag}(a,b)\), then \(K = \text{diag}(\kappa_S/k, \kappa_F/k)\), \(Q = \text{diag}(q_F/k, q_S/k)\), the spin-rotation matrices \(D_\alpha, D_\beta\) between the quantization axis in the FI and the \(z\) axis, and the phase matrices \(\Phi_{S,F}\) are

\[
D_\varphi = \begin{pmatrix}
e^{\frac{i\varphi}{2}} & 0 \\
0 & e^{-\frac{i\varphi}{2}}
\end{pmatrix}, \quad D_\alpha = \begin{pmatrix}
\cos \frac{\alpha}{2} & -\sin \frac{\alpha}{2} \\
\sin \frac{\alpha}{2} & \cos \frac{\alpha}{2}
\end{pmatrix}, \quad \Phi_{S,F} = \begin{pmatrix}
e^{i\varphi_{S,F}} & 0 \\
0 & e^{-i\varphi_{S,F}}
\end{pmatrix} \tag{3.3}
\]

and the spin-rotation matrix \(D_\beta\) at the FI-F interface results from \(Q^{-\frac{1}{2}} D_\alpha K D_{\beta,S}^\dagger Q^{-\frac{1}{2}} = D_{\beta,Z} D_{\beta,F}^\dagger\) with \(Z = \text{diag}(\zeta, \zeta)\). The angle \(\beta\) vanishes for \(\alpha = 0\), and \(\zeta\) varies from \(\kappa_S/k\) to \(\kappa_F/q\) at \(\alpha = \pi\), correspondingly \(\zeta\) varies from \(\kappa_S/q\) to \(\kappa_F/k\). Also, \(\Phi_S = (\sigma_0 - iK)/(\sigma_0 + iK), \Phi_F = (\sigma_0 - iZ)/(\sigma_0 + iZ), \nu_S = \sqrt{2}(\sigma_0 + K^2), \nu_F = \sqrt{2}(\sigma_0 + Z^2), \) and the tunneling amplitude is \(T = V A\) with \(V = \text{diag}(e^{-\kappa_F d}, e^{-\kappa_S d})\) and the real-valued mismatch matrix \(A = KD_{\alpha,S} Q^{-\frac{1}{2}} D_{\beta,F} = D_{\alpha,S} Q^{-\frac{1}{2}} D_{\beta,F}\), of which the off-diagonal elements appear for \(\alpha \neq 0, \pi\) only.

One can see from equation (3.2) that the spin-mixing phases, which appear in the reflection amplitudes, also enter the transmission amplitudes; in the tunneling limit they contribute from
each side of the interface one half \cite{68}. Furthermore, one should notice that the interface is described by two spin-rotation matrices: one given by the misalignment of the FI magnetic moment with the z axis in spin space, and one which is combined from the magnetization in F and the magnetic moment in FI. The latter appears because the wave function at the FI-F interface is delocalized over the FI-F interface region on the scale of the Fermi wavelength and experiences an averaged effective exchange field, which lies in the plane spanned by the z axis and the direction of the FI magnetic moment (same $\vec{D}_s$ in equation (3.2)).

Pair correlation functions $f$ are related to coherence functions by $f = -2\pi i\gamma_{\sigma}(\sigma_0 - \bar{\gamma}_{\sigma})^{-1}$, with $f$, $\gamma$ and $\bar{\gamma}$ 2 x 2 matrices in spin space \cite{101}. When both are small (near $T_c$ or induced from a reservoir by tunneling through a barrier), $f$ and $\gamma$ are proportional. Assuming an incoming singlet coherence function $\gamma_0$ in S, the coherence functions reflected back into S and the ones transmitted to F can be calculated to linear order in the pair tunneling amplitude according to

$$\gamma_{\sigma}^{(S)}_{\text{out}} = S_{11} \begin{pmatrix} 0 & \gamma_0 \\ -\gamma_0 & 0 \end{pmatrix} S_{11}^{*}, \quad \gamma_{\sigma}^{(F)}_{\text{out}} = S_{21} \begin{pmatrix} 0 & \gamma_0 \\ -\gamma_0 & 0 \end{pmatrix} S_{12}^{*}. \tag{3.4}$$

For the reflected amplitude in S one obtains ($\vartheta_S = \vartheta_{F}^{\uparrow} - \vartheta_{F}^{\downarrow}$)

$$\gamma_{\sigma}^{(S)}_{\text{out}}^{(F)} \approx \frac{C}{\gamma_0} \sin \left( \frac{\vartheta_S}{2} \right) \left[ \sqrt{\frac{T_{F}^{\uparrow}}{q_\uparrow}} \sin(\alpha) - \sin(\beta) \right] + \sin \left( \frac{\vartheta_S + \vartheta_{F}^{\uparrow}}{2} \right) \sin(\beta) \tag{3.6}$$

$$\gamma_{\sigma}^{(F)}_{\text{out}}^{(F)} \approx \frac{C}{\gamma_0} \sin \left( \frac{\vartheta_S}{2} \right) \left[ \sqrt{\frac{T_{F}^{\uparrow}}{q_\uparrow}} \sin(\alpha) - \sin(\beta) \right] + \sin \left( \frac{\vartheta_S + \vartheta_{F}^{\uparrow}}{2} \right) \sin(\beta) \tag{3.7}$$

with $C = 4e^{-\frac{(\kappa_\uparrow + \kappa_\downarrow)}{2} T_{F}^{\uparrow} |\mu_{S\downarrow}^{\uparrow} \mu_{F}^{\uparrow} - \mu_{S\uparrow}^{\uparrow} \mu_{F}^{\downarrow}|}$ and $\vartheta_{F}^{\uparrow}$ is the wavevector $\epsilon_{k_F^{\uparrow} q_{\uparrow}}$ in F and are suppressed (except in ballistic one-dimensional channels) due to dephasing after a short distance $1/|q_\downarrow - q_\uparrow|$ away from the interface. Importantly, from (3.6) and (3.7) it is visible that the equal-spin amplitudes acquire phases $\pm \varphi$ from the azimuthal angle in spin space, which play an important role in Josephson structures with half-metallic ferromagnets \cite{83,85} and with strongly spin-polarized ferromagnets when two interfaces with different azimuthal angles $\varphi_1$ and $\varphi_2$ are involved \cite{102,103}.

The misalignment of FI with F also induces a spin-flip term during reflection on the ferromagnetic side of the interface, which creates for an F incoming amplitude $\gamma_{\uparrow \downarrow}$ a reflected amplitude $\gamma_{\downarrow \uparrow} = \gamma_{\uparrow \downarrow} e^{-2i\varphi} \sin^2 \frac{\vartheta_S}{2} \sin^2 \frac{\vartheta_{F}^{\uparrow}}{2} \sin^2 \frac{\vartheta_{F}^{\downarrow}}{2}$, and for an incoming amplitude $\gamma_{\downarrow \uparrow}$ a reflected amplitude $\gamma_{\uparrow \downarrow} = \gamma_{\downarrow \uparrow} e^{-2i\varphi} \sin^2 \frac{\vartheta_S}{2} \sin^2 \frac{\vartheta_{F}^{\uparrow}}{2} \sin^2 \frac{\vartheta_{F}^{\downarrow}}{2}$ in this case, twice the azimuthal angle $\pm \varphi$ enters.

(c) Andreev bound states in S-FI-HM-FI’-S junctions

For an S-FI-HM interface with a half-metallic ferromagnet (HM) in which one spin-band (e.g. spin-down) is insulating and the other itinerant, equation (3.6) is modified to \cite{85}

$$\gamma_{\downarrow \uparrow}^{(F)}_{\text{out}} \approx -4ie^{-i\varphi} e^{-\frac{(\kappa_\uparrow + \kappa_\downarrow)}{2} T_{F}^{\uparrow} |\mu_{S\downarrow}^{\uparrow} \mu_{F}^{\uparrow} - \mu_{S\uparrow}^{\uparrow} \mu_{F}^{\downarrow}|} \sin \left( \frac{\vartheta_S}{2} \right) \sin(\alpha). \tag{3.8}$$

The same equation also holds at an S-FI-F interface when the conserved wavevector $k_F$ is such that only one spin-projection on the magnetization axis is itinerant in F. For strongly spin-polarized F this is an appreciable contribution to the transmitted pair correlations.
In order to describe Josephson structures, it is necessary to handle the spatial variation (and possibly phase dynamics) of both coherence amplitudes and superconducting order parameter (which are coupled to each other). For this, a powerful generalization of the $2 \times 2$ spin-matrix coherence functions has been introduced [78,101], based on previous work for spin-scalar functions in equilibrium [104,105] and non-equilibrium [45]. The generalized coherence functions $\gamma(p_F, \varepsilon, t)$ and $\tilde{\gamma}(p_F, \varepsilon, t)$ fulfill transport equations
\begin{align}
\text{i}h \mathbf{v}_F \cdot \nabla \gamma + 2 \varepsilon \gamma &= \gamma \gamma (\Sigma \circ \gamma - \gamma \circ \Sigma) - \Delta, \quad (3.9) \\
\text{i}h \mathbf{v}_F \cdot \nabla \tilde{\gamma} - 2 \varepsilon \tilde{\gamma} &= \tilde{\gamma} \gamma (\Sigma \circ \gamma - \gamma \circ \Sigma) - \tilde{\Delta} \quad (3.10)
\end{align}
with $p_F$ a Fermi momentum vector, $\Sigma$ and $\Delta$ include particle-hole diagonal and off-diagonal self-energies and mean fields (e.g. for impurity scattering; $\Delta$ includes the superconducting order parameter), and external potentials. The time-dependent case is included by the convolution over the internal energy-time variables in Wigner coordinate representation,
\begin{equation}
(A \circ B)(\varepsilon, t) \equiv e^{\frac{i}{\hbar} \int_{0}^{t} \int_{0}^{\infty} (\partial^{\alpha}_{\varepsilon} \partial^{\beta}_{\gamma} - \partial^{\alpha}_{\gamma} \partial^{\beta}_{\varepsilon}) A(\varepsilon, t) B(\varepsilon, t). \quad (3.11)
\end{equation}
In the time-independent case it reduces to a simple spin-matrix product. Furthermore, the particle-hole conjugation operation is defined by $\tilde{A}(p_F, \varepsilon, t) = A^{*}(-p_F, \varepsilon, -t)$. Particle-hole diagonal $[\gamma = -\text{i}(2\mathbf{V} - \sigma_0)]$ and off-diagonal $[\tilde{\gamma} = -\text{i}(2\mathbf{V} - \sigma_0)]$ pair correlation functions (quasiclassical propagators) are obtained in terms of these coherence functions by solving the following algebraic (or in the time-dependent case, differential) equations
\begin{equation}
\mathbf{V} = \sigma_0 + \gamma \circ \tilde{\gamma} \circ \mathbf{V}, \quad \tilde{\mathbf{V}} = \sigma_0 + \tilde{\gamma} \circ \gamma \circ \tilde{\mathbf{V}}, \quad \mathbf{F} = \gamma + \gamma \circ \tilde{\gamma} \circ \mathbf{F}, \quad \tilde{\mathbf{F}} = \tilde{\gamma} + \tilde{\gamma} \circ \gamma \circ \tilde{\mathbf{F}}. \quad (3.12)
\end{equation}
The Fermi-momentum-resolved density of states is $N/N_F = \text{Re}[\mathcal{V}_{\uparrow \uparrow} + \mathcal{V}_{\downarrow \downarrow}] - 1$, with $N_F$ the density of states in the normal state. A Fermi surface average yields the local density of states.

In figure 5 an example for a fully self-consistent calculation of the spectrum of subgap Andreev states in a S-FI-HM-FI'-S junction is shown, obtained by solving equations (3.9), (3.10) as well as the self-consistency equation for the superconducting order parameter in S. For details of the calculation and parameters see [68,92]. The ferromagnetic insulating barriers FI and FI' are taken identical in this calculation, and the spectra are shown at the half-metallic side of the S-FI-HM interface. The most prominent feature in these spectra is an Andreev quasiparticle band centered over the junction, for quasiparticles with normal impact ($k_0 = 0$), at $T = 0.05T_F$. All states are fully spin-polarized. (a) and (c) Dispersion of the maxima of the DOS as function of phase difference. Regions with low DOS are white, regions of high DOS (bands of Andreev bound states) are shaded. The signs indicate the direction of the current carried by the Andreev states. (b) and (d) show spectra for a fixed phase difference, both for positive (full lines) and negative (dashed lines) propagation direction. (a)-(b) is for a large misalignment between FI and HM, and (c)-(d) for a small misalignment. (b) and (d) from [68]. Copyright (2003) by the American Physical Society.
the two S banks determine the direction of current carried by these states. This direction is indicated in the figure by + and − signs. In panels (b) and (d) for a selected phase difference the Fermi-momentum-resolved spectra for positive and negative propagation direction are shown. These spectra, multiplied with the equilibrium distribution function (Fermi function) determine the positive and negative contributions of the Andreev bound states to the Josephson current in the system. Spectra in (b) and (d) are shown for normal impact direction (\( k_\parallel = 0 \)). An integration over \( k_\parallel \) gives the local density of states.

For the case that one can neglect the variation of the order parameter \( \Delta \) in S, one can derive quite a number of analytical expressions [78,83,107]. Examples for integrated spectra are shown in figure 6, taken from Ref. [78]. In (a) the well-known spectrum of de Gennes-Saint James bound states is seen for an S-N-S junction [108], showing a dispersion with phase bias \( \varphi_0 \). At \( \Delta \chi = \pi \) a zero energy bound state is present, which is a topological feature of the particular Andreev differential equations describing this system, for real-valued order parameters that change sign when going from the left S reservoir to the right S reservoir. The origin is the same as for the midgap state in polycrystalline [109], which is governed by similar differential equations. Such midgap states have been studied in more general context by Jackiw and Rebbi [110] and ultimately have their deep mathematical foundation in the Atiyah-Patodi-Singer index theorem [111]. For the S-FI-HM-FI-S junction, shown in (b)-(d), the prominent feature for all values of \( \Delta \chi \) is the band of Andreev states centered around zero energy. The width \( W \) of this low-energy Andreev band depends on the parameter \( P = \sin(\varphi_0/2)\sin(\alpha) \) and can be calculated for the limit of short junctions \( L \to 0 \) for \( t = 1 \) as [78]

\[
W(\Delta \chi = 0) = 2|\Delta|\sqrt{1 - P^2}, \quad W(\Delta \chi = \pi) = |\Delta|(\sqrt{2} - P^2 - P).
\]  

(3.13)

In the limit \( P \to 0 \) this gives \( W(\Delta \chi = 0) = 2|\Delta| \) and \( W(\Delta \chi = \pi) = \sqrt{2}|\Delta| \). Note that compared to the S-N-S junction, the low-energy features disperse in opposite direction when increasing \( \Delta \chi \) for the S-FI-HM-FI-S junction. This means that the current flows in opposite direction, and typically a \( \pi \)-junction is realized for identical interfaces. If the azimuthal interface misalignment angles \( \varphi \) differ by \( \pi \) in FI and FI’, then this phase would add to \( \Delta \chi \) according to equation (3.8) and a zero-junction would be realized. In the general case, a \( \phi \)-junction appears, both for ballistic and diffusive structures [83,85,112].
(d) Spin torque in S-FI-N-FI’-S’ structures

Andreev states play also an important role in the non-equilibrium spin torque and in the spin-transfer torque in S-F structures [113–116]. Zhao and Sauls found that in the ballistic limit the equilibrium torque is related to the spectrum of spin-polarized Andreev bound states, while the ac component, for small bias voltages, is determined by the nearly adiabatic dynamics of the Andreev bound states [117,118]. The equilibrium spin-transfer torque \( \tau_{eq} \) in an S-FI-N-FI’-S’ structure is related to the Josephson current \( I_s \), the phase difference between S and S’, \( \Delta \chi \), and the angle \( \Delta \alpha \) between FI and FI’, by [119]

\[
\hbar \frac{\partial I_s}{\partial \Delta \alpha} = 2e \frac{\partial \tau_{eq}}{\partial \Delta \chi}.
\]

Similarly, as the dispersion of the Andreev bound states with superconducting phase difference \( \Delta \chi \) yields the contribution of the bound state to the Josephson current, the dispersion of the Andreev states with \( \Delta \alpha \) yields the contribution of this state to the spin current for spin polarization in direction of the spin torque. The dc spin current shows subharmonic gap structure due to multiple Andreev reflections (MAR), similar as for the charge current in voltage biased Josephson junctions [120,121]. For high transmission junctions the main contribution to the dc spin current comes from consecutive spin rotations according to equation (2.6) when electrons and holes undergo MAR [118] (see figure 7a).

Turning to ac effects, for a voltage \( eV \ll \Delta \) the time evolution of spin-transfer torque is governed by the nearly adiabatic dynamics of the Andreev bound states. However, the dynamics of the bound state spectrum leads to non-equilibrium population of the Andreev bound states, for which reason the spin-transfer torque does not assume its instantaneous equilibrium value [118]. For the occupation to change, the bound state energy must evolve in time to the continuum gap edges, where it can rapidly equilibrate with the quasiparticles, similar as in the adiabatic limit of ac Josephson junctions [122]. An example of the adiabatic time evolution of the spin torque is shown in figure 7b.

The effect of rough interfaces and of spin-flip scattering on spin-transfer torque in the presence of Andreev reflections has been discussed by Wang, Tang, and Xia [123]. For diffusive structures see [124]. Magnetization dynamics has been also addressed recently [125–127].

Andreev sidebands in a system with two superconducting leads coupled by a precessing spin proved important to study spin-transfer torques acting on the precessing spin [128]. Spin-polarized Shapiro steps were studied in [129].

Figure 7. (a) Subgap excitation undergo multiple multiple Andreev reflections (MAR), thus gaining multiples of the voltage \( eV \). Whereas charge is transferred to Cooper pairs during each Andreev reflection, spin can only escape the N region at energies above the gap. During each reflection particles and holes experience a spin rotation due to spin-dependent phase shifts. (b) Time evolution of the spin-transfer torque on FI in the adiabatic limit, for \( \alpha = \pi/2 \) and two values of spin-dependent phase shifts, at zero temperature. From [118]. 4. Andreev spectroscopy in F-S and F-S-F′ structures

Andreev point contact spectra in S-F structures are modified with respect to those in S-N structures due to spin-filtering effects and the spin-sensitivity of Andreev scattering [84,130–135]. Spin-dependent phase shifts also crucially affect Andreev point contact spectra [72,136–141]. Point contacts have lateral dimensions much smaller than the superconducting coherence lengths of the ferromagnet on the contact plane. For each value of\( e = 1, ..., \nu \) for each given value of \( k_\parallel \), in the superconductor. Thus, in the normal state the current \( I \) is positive when the voltage in the ferromagnet is positive. The various currents can be expressed as

\[
I_X = -A \int_{\mathcal{A}_F} \frac{d^2S(k_\parallel)}{(2\pi)^2} \int_{-\infty}^{\infty} \frac{d\epsilon}{2\pi} \epsilon j_X, \tag{4.4}
\]

where \( e = -|e| \) is the charge of the electron, \( A \) is the contact area, and \( \mathcal{A}_F \) is the projection of the Fermi surfaces in the ferromagnet on the contact plane. For each value \( k_\parallel \), there will be a number of (spin-polarized) Fermi surface sheets involved in the interface scattering (in the simplest case spin-up and spin-down, or only spin-up), and the dimension and structure of the scattering matrix will depend on how many Fermi surface sheets are involved. The sum over \( \alpha \) and \( \beta \) runs over those Fermi surface sheets 1,...,\( \nu \) for each given value of \( k_\parallel \). In the superconductor I assume for simplicity that only one Fermi surface sheet is involved for each \( k_\parallel \). The reflection and transmission amplitudes for each \( k_\parallel \) are related to the scattering matrix as

\[
S(12;34) = \begin{pmatrix} R_{12} & T_{14} \\ T_{32} & -R_{34} \end{pmatrix} \tag{4.5}
\]

where directions 1 and 2 refer to the superconductor, and 3 and 4 to the ferromagnet. \( R_{12} \) is a \( 2 \times 2 \) spin matrix, \( R_{14} \) is a \( \nu \times \nu \) matrix with elements \( R_{\alpha\beta} \), \( T_{14} \) is a \( 2 \times \nu \) matrix with elements \( T_{1\beta} \), and \( T_{32} \) is a \( \nu \times 2 \) matrix with elements \( T_{\alpha2} \). Note that the theory presented here does not rely on any modeling of interface potentials or exchange fields, nor does it employ any free-electron dispersions in the conducting leads. It rather works with the fully renormalized interface
scattering matrix (4.5) as well as with the fully renormalized Fermi surface data. The spectral current densities $j_{\delta}$ are given by (I restrict formulas here and below to stationary situations)

$$j_1 = \sum_{\beta} \delta x_{\beta}, \quad j_R = \sum_{\alpha\beta} R_{\alpha\beta} - T_{\alpha2} v_2 \gamma_2 \bar{R}_{21} \bar{\gamma}_1 T_{1\beta} \delta x_{\beta},$$

$$j_{AR} = \sum_{\alpha2} [T_{\alpha2} v_2 \gamma_2 \bar{R}_{21} \bar{\gamma}_1 T_{1\beta}]^2 \delta x_{\beta}, \quad v_2 = (\sigma_0 - \gamma_2 \bar{R}_{21} \bar{\gamma}_1 R_{12})^{-1},$$

(4.6)

(4.7)

where $\delta x_{\beta}$ and $\delta x_{\beta}$ are the differences between the distribution functions in the ferromagnet and in the superconductor. If there is no spin-accumulation present, they are independent of the index $\beta$ and given by

$$\delta x(V, T; \epsilon) = \sigma_0 \left[ \tanh \left( \frac{\epsilon - eV}{2k_B T} \right) - \tanh \left( \frac{\epsilon}{2k_B T S} \right) \right], \quad \delta x(V, T; \epsilon) = \delta x(V, T; -\epsilon),$$

(4.8)

with $T_S$ the temperature in the superconductor. Equations (4.6)-(4.7) are valid for general normal-state scattering matrices $S$, and can be applied to non-collinear magnetic structures. For the case that all reflection and transmission amplitudes are spin-diagonal, considering an isotropic singlet superconductor with order parameter $\Delta = \Delta_0 i \tau_2$, and assuming on the superconducting side of the interface a spin-mixing angle $\vartheta$, these expressions are explicitly given by

$$j_R = \left[ |v_{0+}|^2 |r_+ - r_+ e^{i\vartheta_0/2}|^2 + |v_{0-}|^2 |r_+ - r_+ e^{-i\vartheta_0/2}|^2 \right] \delta x,$$

$$j_1 = 2\delta x,$$

$$j_{AR} = (t_1 t_2 \gamma_0)^2 \delta x,$$

(4.9)

(4.10)

with $\gamma_0 = -|\Delta_0|/(\epsilon + i \Omega)$, $\Omega = \sqrt{|\Delta_0|^2 - \epsilon^2}$, $v_{0\pm} = (1 - \gamma_0^2 t_1 t_2 e^{\pm i \vartheta_1})^{-1}$, and the energy $\epsilon$ is assumed to have an infinitesimally small positive imaginary part. Andreev resonances arise for energies fulfilling $1 = \gamma_0^2 r_1 r_2 \epsilon^{\pm \vartheta}$ (in agreement with the discussion in section 2(b) for $d = 0$).

On the other hand, for half-metallic ferromagnets the Andreev reflection contribution is zero in collinear magnetic structures. In non-collinear structures, however, the process of spin-flip Andreev reflection takes place, introduced in reference [136], and illustrated there in figure 11. Spin-flip Andreev reflection is the only process providing particle-hole coherence in a half-metallic ferromagnet. Such structures are described by the theory developed in appendix C of [78]. Application of this theory to experiment on CrO$_2$ is provided in [72,140]. A generalization to strongly spin-polarized ferromagnets with two itinerant bands is given in [136] with application to experiment in [137].

In figure 8 selected results are shown. In (a) and (b) it is demonstrated that the spin-mixing angle can acquire large values if a smooth spatial interface profile is used instead of an atomically

Figure 8. (a) Shape function of the (spin-averaged) interface barrier potential. A shape parameter $\alpha = 0 \ldots 0.7 \lambda_F$ increases for increasing smoothness. (b) Spin-mixing angle $\sigma_3$ as a function of $|k_z|$ for the shape functions in (a). $\sigma_3$ increases with increasing $\sigma$. (c) The differential conductance of an F-FI-S structure with various degrees of smoothness if the FI barrier, at $T = 0$: $\alpha$ increases from back to front in steps of 0.1 $\lambda_F$. (d) Temperature dependence of the zero-voltage conductance of an HM-FI-S point contact as predicted by (d) the modified BTK model [133] and (e) the spin-active interface model [78,136]. Adapted from [72,136]. Copyright (2010) by the American Physical Society.
clean interface. Correspondingly, in (c) Andreev resonances are more pronounced for smoother interfaces. In (d) and (e) a comparison of the model by Mazin et al. [133] for various spin polarizations \( P \) with the spin-mixing model for \( P=100\% \) and various spin-mixing angles \( \vartheta \) shows that the two can be experimentally differentiated by studying the low-temperature behavior [72].

In an experiment by Visani et al. [142] geometric resonances (Tomasch resonances and Rowell-McMillan resonances) in the conductance across a \( \text{La}_0.7\text{Ca}_{0.3}\text{Mn}_3\text{O}_4/\text{YBa}_2\text{Cu}_3\text{O}_7 \) interface were studied, demonstrating long-range propagation of superconducting correlations across the half metal \( \text{La}_0.7\text{Ca}_{0.3}\text{Mn}_3\text{O}_4 \). The effect is interpreted in terms of spin-flip Andreev reflection (or, as named by the authors of [142], “equal-spin Andreev reflection”).

Spin-dependent scattering phases qualitatively affect the zero- and finite-frequency current noise in S-F point contacts [143,144]. It was found that for weak transparency noise steps appear at frequencies or voltages determined directly by the spin dependence of scattering phase shifts.

(b) Andreev bound states in non-local geometry

A particular interesting case is that of two F-S point contacts separated by a distance \( L \) of the order of the superconducting coherence length. This is effectively an F-S-F' system, or if barriers are included, an F-FI-S-FI'-F' system. In this case, for a ballistic superconductor, one must consider separately trajectories connecting the two contacts [145]. Along these trajectories the distribution function is out of equilibrium, and equations (4.1)-(4.2) must be solved. In addition, the coherence functions at these trajectories experience both ferromagnetic contacts, and are consequently separated trajectories connecting the two contacts [145]. Along these trajectories the distribution function is out of equilibrium, and equations (4.1)-(4.2) must be solved. In addition, the coherence functions at these trajectories experience both ferromagnetic contacts, and are consequently different from the homogeneous solutions \( \tilde{\gamma}_0, \tilde{\gamma}_0 \) of all other quasiparticle trajectories.

The current on the ferromagnetic side of one particular interface (positive in direction of the superconductor), can be decomposed in an exact way,

\[
I = I_1 - I_R + I_{AR} - I_{EC} + I_{CAR} \tag{4.11}
\]

where the various terms are the incoming current, \( I_1 \), the normally reflected part, \( I_R \), the Andreev reflected part, \( I_{AR} \), and the two non-local contributions due to elastic co-tunneling, \( I_{EC} \) and crossed Andreev reflection, \( I_{CAR} \).

There will be contributions from trajectories in the superconductor which do not connect the two contacts. These will be described by equations (4.6)-(4.7) above. Here, I will concentrate on the non-local contributions, which arise from the particular trajectories connecting the two contacts. Assuming the area of each contact much smaller than the superconducting coherence length (however larger than the Fermi wavelength, such that the momentum component parallel to the contact interfaces are approximately conserved), one can identify all trajectories connecting the two contacts, treating only one and scaling the result with the contact area. The solid angle from a point at the first contact to the area \( \mathcal{A}' \) of the second contact is given by \( \delta \Omega = A_2/L^2 \), where \( A_2 \) is the projection of the area of the second contact to the plane perpendicular to the line \( 2, 2' \) which connects the contacts (see figure 9 for the notation).

Using the conservation of \( k_\| \), and that consequently \( d^2S(k_\|) = d^2S(p_{F2})|\hat{n} \cdot v_{F2}|/|v_{F2}| = d^2S(p_{F0})|\hat{n} \cdot v_{F0}|/|v_{F0}| \) (where \( \hat{n} \) is the contact surface normal), one can express the currents as

\[
I_X = -\frac{d^2S}{d\Omega} \left| \frac{A_2A'_2}{(2\pi\hbar)^3L^2} \right| \int_{-\infty}^{\infty} \frac{d\xi}{2} e^{jX}, \tag{4.12}
\]

where \( p_{F2} \) is the particular Fermi momentum in the superconductor corresponding to a Fermi velocity in direction of the line 2, 2' (I assume for simplicity that only one such Fermi momentum exists), and \( d^2S/d\Omega \) is the differential fraction of the Fermi surface of the superconductor per solid angle \( \Omega \) in direction of the Fermi velocity \( v_{F2} \) that connects the two contacts. Note that \( d^2S/d\Omega \) is the same at both contacts for superconductors with inversion symmetry, as then this quantity is equal at \( p_{F2} \) and \(-p_{F2} \). Reversed directions are denoted by an overline: \( p_{F2} = -p_{F2} \) etc. Let us introduce scattering matrices \( S(12; 34) \) as well as \( S(21, 43) \) at the left interface, the latter being equal to \( S(12; 34) \) for materials with centrosymmetric symmetry groups, which I consider.
Figure 9. Illustration of notation used in text. For brevity of notation I sometimes omit the label 3 and 4, implying that $\alpha$ then means $3\alpha$ and $\beta$ means $3\beta$. E.g. in the right picture the ferromagnet has two spin Fermi surfaces (red and blue), labeled by $\alpha \in \{3\uparrow, 3\downarrow\}$ and $\beta \in \{4\uparrow, 4\downarrow\}$ etc. The superconductor’s Fermi surface is drawn in green.

here. Analogously, for the right interface let us introduce the scattering matrices $S'(2'1'; 4'3') = \mathcal{S}'(1'2'; 3'4')$. The scattering matrices for holes are related to the scattering matrices for particles by $S(21; 43) = S(21; 43)^\dagger$ etc. One obtains for this case

$$j_1 = \sum_\beta \delta x_\beta + \sum_\alpha \delta x_\alpha$$

(4.13)

$$j_R = \sum_\beta |R_\beta \alpha - T_{\beta \alpha} v_2 \gamma_2 \tilde{R}_{21} \gamma_1 T_{1\beta}|^2 \delta x_\beta + \sum_\beta |R_\beta \alpha - T_{\beta \alpha} v_1 \gamma_1 \tilde{R}_{12} \gamma_2 T_{2\beta}|^2 \delta x_\alpha$$

(4.14)

$$j_{AR} = \sum_\alpha \sum_\beta |T_{\alpha \beta} v_2 \gamma_2 \tilde{T}_{2\alpha} |^2 \delta \tilde{x}_\alpha + \sum_\beta |T_{\beta \alpha} v_1 \gamma_1 \tilde{T}_{1\beta} |^2 \delta \tilde{x}_\beta$$

(4.15)

$$j_{EC} = \sum_\alpha \sum_\beta |T_{\alpha \beta} u_{22} \gamma_2 T_{2\alpha} |^2 \delta x_\alpha + \sum_\beta |T_{\beta \alpha} v_1 \gamma_1 \tilde{R}_{12} \bar{u}_{22} \tilde{R}_{2\alpha} |^2 \delta \tilde{x}_\beta$$

(4.16)

$$j_{CAR} = \sum_\alpha \sum_\beta |T_{\alpha \beta} u_{22} \gamma_2 T_{2\alpha} |^2 \delta \tilde{x}_\alpha + \sum_\beta |T_{\beta \alpha} v_1 \gamma_1 \tilde{R}_{12} \bar{u}_{22} \tilde{R}_{2\alpha} |^2 \delta \tilde{x}_\beta$$

(4.17)

where the vertex corrections due to multiple Andreev processes are $v_2 = (\sigma_0 - \gamma_2 \tilde{R}_{21} \gamma_1 R_{12})^{-1}$ and $v_1 = (\sigma_0 - \gamma_1 \tilde{R}_{12} \gamma_2 R_{21})^{-1}$. For unitary order parameters $(\Delta \tilde{A} \sim \sigma_0)$, let us define $\Omega \sigma_0 = [-\Delta \tilde{A} \epsilon - (\varepsilon + i0^+)^2 \sigma_0]^\dagger$ as well as $\gamma = -\Delta / (\varepsilon + i\Omega)$. Using the amplitudes

$$\Gamma_2'' = R_{22''} \gamma_1 \tilde{R}_{22''}, \quad \tilde{\Gamma}_2'' = \bar{R}_{22''} \gamma_1 \bar{R}_{22''},$$

(4.18)

and denoting with $L$ the distance between 2 and 2',

$$u_{22'} = \left[\sigma_0 c_{2'} + i \frac{\Gamma_2'' \Delta_{2'} - \sigma_0 \varepsilon}{\Omega_{2'}}\right]^{-1}, \quad \gamma_2 = u_{22'} \left[\Gamma_2'' c_{2'} + i \frac{\Delta_{2'} + \Gamma_2'' \varepsilon}{\Omega_2'} \right]$$

(4.19)

$$\bar{u}_{22'} = \left[\sigma_0 c_{2'} - i \frac{\Gamma_2'' \Delta_{2'} - \sigma_0 \varepsilon}{\Omega_{2'}}\right]^{-1}, \quad \gamma_2 = \bar{u}_{22'} \left[\Gamma_2'' c_{2'} - i \frac{\Delta_{2'} - \Gamma_2'' \varepsilon}{\Omega_2'} \right]$$

(4.20)

with $c_2' = \cosh(\Omega_2 L / h v_{F,2'})$ and $s_2' = \sinh(\Omega_2 L / h v_{F,2'})$. For the distribution functions one obtains for the two leads

$$\delta \tilde{x}_\alpha = \delta x_\alpha = \delta x(V, T; \varepsilon), \quad \delta \tilde{x}_\beta = \delta x(V, T; -\varepsilon),$$

(4.21)

$$\delta x_{2'} = \delta x_{2'} = \delta x(V', T'; \varepsilon), \quad \delta \tilde{x}_{2'} = \delta \tilde{x}_{2'} = \delta x(V', T'; -\varepsilon).$$

(4.22)

Here, $T_0$ is the temperature in the superconductor, $T$ and $V$ are temperature and voltage in the left lead, and $T'$ and $V'$ are temperature and voltage in the right lead. The voltages are
measured with respect to the superconductor. The expressions appearing in equations (4.13)-(4.17) have an intuitive interpretation, and selected processes are illustrated in figure 10. These terms involve propagation of particles or holes, represented as full lines and dashed lines in the figure. Certain processes involve conversions between particles and holes, accompanied by the creation or destruction of a Cooper pair (loops in the figure), and correspond to the factors $\gamma_L, \gamma_Y, \tilde{\gamma}_1,$ and $\tilde{\gamma}_2$ in (4.14)-(4.17). Propagation of particles or holes between the left and right interface is represented in these equations by the factors $u_{22'}$ and $\bar{u}_{22'}.$ Vertex corrections $v_3$ and $v_4$ correspond to multiple Andreev reflections at either interface. The factors $\gamma_2$ and $\tilde{\gamma}_2$ combine propagation between the two interfaces with Andreev reflections at the other interface.

As an example, for an isotropic singlet superconductor and collinear arrangement of the magnetization directions, one obtains

\[
\begin{align*}
 j_l &= \delta x, \\
 j_R &= \left[ 2|v_+|^2 |r_\uparrow - r_\downarrow e^{i\theta} \gamma_0\gamma_\uparrow|^2 + 2|v_-|^2 |r_\downarrow - r_\uparrow e^{-i\theta} \gamma_0\gamma_-|^2 \right] \delta x \\
 j_{AR} &= (t_1 t_2) \left[ |v_+|^2 (|\gamma_\uparrow|^2 + |\gamma_0|^2) + |v_-|^2 (|\gamma_-|^2 + |\gamma_0|^2) \right] \delta \tilde{\epsilon} \\
 j_{EC} &= \left[ (t_1 t_2')^2 |v_+ u_+|^2 \left( 1 + |\gamma_0|^2 \right) (r_\uparrow r_\uparrow')^2 \right] + \left[ (t_1 t_2')^2 |v_- u_-|^2 \left( 1 + |\gamma_0|^2 \right) (r_\downarrow r_\downarrow')^2 \right] \delta \tilde{\epsilon}' \\
 j_{CAR} &= |\gamma_0|^2 \left[ (t_1 t_2')^2 |v_+ u_+|^2 \left( (r_\uparrow')^2 + (r_\uparrow)^2 \right) + (t_1 t_2')^2 |v_- u_-|^2 \left( (r_\downarrow')^2 + (r_\downarrow)^2 \right) \right] \delta \tilde{\epsilon}'' \\
\end{align*}
\]

where I defined (with $s \equiv s_2$ and $c \equiv c_2$)

\[
\begin{align*}
 I_{\pm} &= r_\uparrow' r_\downarrow e^{\pm i\theta'} \gamma_0, \\
 \gamma_{\pm} &= u_{\pm} \left[ I_{\pm}^2 e^{i(\Delta + I_{\pm}^2 / \Omega)} \right] \\
 u_{\pm} &= \left[ c - i s(\epsilon + I_{\pm}^2 / \Omega) \right]^{-1}, \\
 v_{\pm} &= \left[ 1 - \gamma_{\pm} \gamma_0 r_\uparrow r_\downarrow e^{\pm i\theta} \right]^{-1}. 
\end{align*}
\]

Early studies of nonlocal transport in F-S-F structures include Ref. [146]. In Ref. [73] the nonlocal conductance was explained in terms of the processes discussed above for an F-S-F structure with strong spin-polarization. Andreev bound states appear on both ferromagnet-superconductor interfaces, which decay through the superconductor towards the opposite contact. Parallel and antiparallel alignment of the magnetizations lead to qualitatively different Andreev spectra. The non-local processes have a natural explanation in terms of overlapping spin-polarized Andreev states. The density of states for the trajectory connecting the two contacts is obtained from

\[
N_\uparrow(\epsilon, x) = \frac{N_F}{2} \frac{\text{Re}}{1 - \gamma_+ (\epsilon, x) \gamma_0 (\epsilon, x, L - x)} \\
1 + \gamma_+ (\epsilon, x) \gamma_0 (\epsilon, x, L - x)
\]

and for $N_\downarrow$ the same expression holds with $+$ and $-$ interchanged. In figure 11 I show an example of such a setup. As can be seen, avoided crossings of Andreev bound states with equal spin
Andreev bound states in an F-S-F structure of the type shown in figure 9. (a): $P = N^{↑} - N^{↓}$ as function of $\varepsilon$ and $\vartheta_R$ at a position in S midway between the contacts, for $L = 2\xi_0$ (with the coherence length of the superconductor $\xi_0 = \hbar v_F/|\Delta|$) and $\vartheta_L = 0.7\pi$. An avoided crossing appears for equally spin-polarized Andreev states, which is absent for opposite polarization. (b) dependence on $L/\xi_0$ for fixed $\vartheta_R = \vartheta_L = 0.7\pi$. (c)-(f): $P$ as function of $\varepsilon$ and $x$ for $L = 2\xi_0$ and $\vartheta_L = 0.7\pi$, and (c) $\vartheta_R = 0.7\pi$, (d) $\vartheta_R = 0.5\pi$, (e) $\vartheta_R = 0.6\pi$, (f) $\vartheta_R = 0.7\pi$. At the avoided crossing all bound states have equal weight at both interfaces. In all other cases the bound states for fixed spin projection are localized at one interface only. In all panels $(r^{↑} r^{↓})_L = (r^{↑} r^{↓})_R = 0$.75. At the avoided crossing all bound states have equal weight at both interfaces. This contrasts the case when bound states have opposite spin polarization, where no avoided crossings appear, and the case when the two S-F interfaces have markedly different spin-dependent phase shifts, in which case bound states do not overlap. Transmission probabilities and bound-state geometries influence CAR and EC processes in the way discussed in [72].

Equations (4.23)-(4.26) have been applied to the study of thermoelectric effects in non-local setups [148,149]. The contributions to the energy current are obtained as

$$I^E = I^C - I^B + I^EC - I^{CAR},$$

(4.30)

where the respective contributions are given by analogous equations as in equations (4.12)-(4.17). Recent experiments show a non-local inverse proximity effect in S-F systems with non-equilibrium transport [156]. A combination of non-local effects in S-F structures with non-equilibrium transport can be another exciting avenue for further applications [159].

Andreev interferometer geometries, in analogy to experiments in S-N structures [17,18], seem to be another exciting avenue for future applications [159].

5. Generalized Andreev Equations

In this section I discuss the physical interpretation of the coherence functions. To this end, I present a generalized set of Andreev equations which is equivalent to equations (3.9)-(3.10). Let us define for each pair of Fermi momenta \( p_F, -p_F \) and corresponding Fermi velocities \( v_F(p_F), v_F(-p_F) \) a pair of mutually conjugated trajectories

\[
\mathbf{R}(\rho) = \mathbf{R}_0 + \hbar v_F(p_F)(\rho - \rho_0), \quad \mathbf{R}(\rho) = \mathbf{R}_1 - \hbar v_F(p_F)(\rho - \rho_1), \quad \rho_0 \leq \rho \leq \rho_1.
\]

(5.1)

Using \( \partial_\rho \equiv \hbar v_F \cdot \nabla \), let us define the following differential operators

\[
\hat{\mathcal{D}} \equiv \begin{pmatrix} -i\sigma_0 \partial_\rho + \Sigma & \Delta \\ -\Delta & i\sigma_0 \partial_\rho - \Sigma \end{pmatrix}, \quad \hat{\mathcal{D}}^\dagger \equiv \begin{pmatrix} -i\sigma_0 \partial_\rho + \Sigma & -\Delta \\ -\Delta & i\sigma_0 \partial_\rho - \Sigma \end{pmatrix}
\]

(5.2)

which fulfill \( \hat{\mathcal{D}} = -\hat{\tau}_1 \hat{\mathcal{D}}^\dagger \hat{\tau}_1 \) (and \( \sigma_0 \) is the unit spin matrix). Let us also define the adjoint operator \( \hat{\mathcal{D}}^\star(\rho, \partial_\rho) = \hat{\mathcal{D}}^\dagger(\rho, -\partial_\rho) \). For a fixed conjugated trajectory pair the set of generalized Andreev equations (retarded and advanced) is,

\[
\hat{\mathcal{D}} \circ \begin{pmatrix} u_R \\ v_R \end{pmatrix} = \varepsilon \begin{pmatrix} v_R \\ u_R \end{pmatrix}, \quad v_R(\rho_1) = -\hat{\tau}_1 \circ u_R(\rho_1), \quad \hat{\mathcal{D}}^\star \circ \begin{pmatrix} u^A \\ v^A \end{pmatrix} = \varepsilon \begin{pmatrix} v^A \\ u^A \end{pmatrix}, \quad v^A(\rho_1) = -\hat{\tau}_1 \circ u^A(\rho_1)
\]

(5.3)

(5.4)

where the boundary conditions at \( \rho = \rho_0 \) and \( \rho = \rho_1 \) for the solutions fulfill the restrictions shown on the right hand side of the equations. Then the relation between the Andreev amplitudes \( u, v, \tilde{u}, \tilde{v} \) and the coherence amplitudes \( \gamma \) and \( \tilde{\gamma} \) is given along the entire trajectories by

\[
\tilde{v}_R,A = -\gamma_R,A \circ u_R,A, \quad v_R,A = -\tilde{\gamma}_R,A \circ u_R,A
\]

(5.5)

with \( \gamma_R \equiv \gamma, \tilde{\gamma}_R \equiv \tilde{\gamma}, \gamma^A \equiv \tilde{\gamma}^A \equiv \gamma \). It is easy to show that the following conservation law along the trajectory holds

\[
\partial_\rho \begin{pmatrix} \tilde{v}_R,A \\ v^A \end{pmatrix} \tilde{\tau}_3 \circ \begin{pmatrix} u_R \\ v^A \end{pmatrix} = 0.
\]

(5.6)

Thus, the matrix inside the curly brackets is given by its value at one point on the trajectory. The off-diagonal elements are zero due to the conditions in Eq. (5.3) for \( \rho_0 \) and \( \rho_1 \), leading to \( (u^A)\circ \tilde{v}_R = (u^A)\circ \tilde{u}_R \) and \( (\tilde{u}_R)^\dagger \circ u^A = (\tilde{v}_R)^\dagger \circ u^A \) along the entire trajectory. The diagonal components \( \partial_\rho [(u^A)^\dagger \circ u^A] = \partial_\rho [(u^A)^\dagger \circ (\tilde{u}_R)^\dagger \circ \tilde{v}_R] = \partial_\rho [(\tilde{u}_R)^\dagger \circ \tilde{v}_R] = \partial_\rho [(u^A)^\dagger \circ u^A] = 0 \) translate into \( \partial_\rho [(u^A)^\dagger \circ u^A] = 0 \) and \( \partial_\rho [(\tilde{u}_R)^\dagger \circ \tilde{v}_R] = 0 \) in particular, at one point \( \rho_0 \leq \rho \leq \rho_1 \). If one writes Eq. (5.3) formally as \( \hat{\mathcal{D}} \circ \hat{U} = \varepsilon \hat{U} \), then the conjugated equation \( \hat{\mathcal{D}}^\dagger \circ \hat{U} = -\varepsilon \hat{U} \) holds with \( \hat{U} = \hat{\tau}_1 \hat{U} \hat{\tau}_1 \), which leads, however, to a system identical to Eq. (5.3). The adjoint equation \( \hat{\mathcal{D}}^\star \circ \hat{U} = \varepsilon \hat{U} \) defines adjoined Andreev amplitudes (left eigenvectors) \( \underline{u}, \underline{v}, \underline{\tilde{u}}, \underline{\tilde{v}} \). These are, however, equivalent to the advanced eigenvectors in Eq. (5.4).

6. Conclusion

I have presented theoretical tools for studying Andreev reflection phenomena and Andreev bound states in superconductor-ferromagnet hybrid structures. Concentrating on ballistic heterostructures with strong spin-polarization, I have formulated theories for point contact spectroscopy and for nonlocal transport, as well as for Andreev states in Josephson structures in terms of coherence functions and distribution functions. The connection to coherence amplitudes
appearing in the solutions of Andreev equations has been made explicit. The formulas for non-local transport have been given in a general form, allowing for non-collinear geometries, and using the normal-state scattering matrix as input.
