ABSTRACT

Two-dimensional (2D) systems have considerably strengthened their position as one of the premier candidates to become the key material for the proposed spintronics technology, in which computational logic, communications and information storage are all processed by the electron spin. In this article, some of the most representative 2D materials including ferromagnetic metals (FMs) and diluted magnetic semiconductor (DMSs) in their thin film form, magnetic topological insulators (TIs), magnetic graphene and magnetic transition metal dichalcogenides (TMDs) are reviewed for their recent research progresses. FM thin films have spontaneous magnetization and usually high Curie temperature ($T_c$), though this can be strongly altered when bonded with semiconductors (SCs). DMS and magnetic TIs have the advantage of easy integration with the existing SC-based technologies, but less robust magnetism. Magnetic ordering in graphene and TMDs are even more fragile and limited to cryogenic temperatures so far, but they are particularly interesting topics due to the desired long spin lifetime as well as the outstanding mechanical and optical properties of these materials.
1. Introduction

The possibility of providing ultimate logic bit by electron’s spin rather than or in addition to its charge has claimed exciting new horizons in physics, material science and electronic engineering. For spin-electronics or spintronics purposes, the materials carrying out the mission must be spin polarized, such as magnetic metals with the broken symmetry between spin down and spin up states near the Fermi level ($E_F$). Historically the spin arrangement has long been investigated within the context of conventional FM and their alloys, while the study of spin generation, relaxation, and spin-orbit coupling in non-magnetic materials has taken off rather recently with the advent of spintronics, and it is here that many novel 2D materials and systems can find their greatest potentials in both science and technology.

The earliest studies of 2D magnetic phenomena can be tracked back to discussions of the interfacial magnetism of FM/SC heterojunctions.[1-18] In this regard, a large portion of the research work over the last two decades was stimulated by the idea of creating a spin field effect transistor (SFET),[19] in which the transport of the electron spins is confined in a high mobility 2D electron gas (2DEG) channel and can be manipulated by the application of a gate voltage. An ideal spin-injected SC would demonstrate high spin polarization, operate at room temperature (RT) and be both robust and easily fabricated for potential high throughput needs. Various FM/SC heterostructures have been hotly investigated since it was demonstrated that substantial spin accumulation and diffusion occurs at the FM/SC interface.[20] The generation of high-spin-polarization current is essential for the SFET concept and therefore the half metallic materials (such as Heusler alloys, magnetite, and chromium dioxide) have been integrated into the hybrid systems.[21-23] Although an full electrical semiconductor spin field effect transistor has recently been demonstrated, all be it at 300 mK and requiring quantum ballistic point contacts.[24] Hybrid systems with ferromagnetic source as sink of spin and an easily gate tuned channel through a high mobility 2D material may offer a route to the SFET at RT.

Van der Waals materials such as graphene, layered TMDs, copper oxides, and iron pnictides with properties dominated by their 2D structural units have become the new focus of 2D magnetism research for the recent few years. The success of single-layer graphene has shown that it is not only possible to exfoliate stable, single-atom or single-polyhedral-thick 2D materials from bulk van der Waals solids, but also that these materials can exhibit fascinating and technologically useful properties. In graphene's band structure, the linear dispersion at the $k$ point gives rise to novel physical phenomena, such as the anomalous quantum Hall effect (AQHE), and has opened up a new category of “Dirac” physics.
Stimulated by the rise of graphene, other 2D crystals including layered hexagonal-boron nitride (h-BN) and TMDs were subsequently demonstrated. The more recently discovered TIs, featured with an insulating bulk gap and gapless Dirac-like band dispersion surface states, are new members of the 2D family. Unlike that of graphene, the electron states of TIs surface are strongly spin–orbit coupled and immune to time-reversal-invariant disorders. Magnetism is not common for the elements consisting Van der Waals materials; however, spin polarization in these materials can still be induced by defects, edge states, magnetic dopants and/or via the proximity to an adjunct magnetic source etc. Compared to FM, they generally have less robust magnetism, but significantly longer spin lifetime or spin coherence length, which are eagerly desired in spintronic engineering. Furthermore, their capacity of integration with FM offers a promising direction toward the development of hybrid devices that can perform logic, communications, and storage within the same material technology.

In this article, a selection of magnetic 2D systems will be introduced, following their historical path of emergence. This includes FM and DMS in their thin film form, magnetic TIs, magnetic graphene and magnetic TMDs, as illustrated in Figure 1. The very recent advances of the study of these materials will be reviewed. This article does in no way try to give a complete overview of the emerging 2D systems, as many of them are still under fast developing till this day; neither is it intended to give deep theoretical descriptions of why the many fascinating phenomena occur in them. The purpose of this article is, instead, to present some of the most important findings of these material systems and to highlight a few hotly debated topics of the contemporary magnetic 2D systems research.

2. Ferromagnetic Metal Thin Films

As the simplest form of magnetic 2D system, transition metal thin films and their alloys have been most thoroughly exploited in the history, as they are relatively easy to grow epitaxially on III-V SCs such as GaAs, InAs and InGaAs etc with relatively small lattice mismatch. [1-18] The magnetic properties of these nanoscale FM thin films are closely linked with two general questions, namely (i) how the magnetic ordering changes with reduced dimensionality and (ii) how the magnetic ordering changes due to electronic bonding at the interface with the SC substrate.

The FM ultrathin films have been found to form metastable phases under certain conditions. While the bulk Co is hcp structure, the bcc Co on the GaAs(100) was demonstrated by Prinz[2, 4, 25] in 1985 and since then many experiments on Co/GaAs were reported with inconsistency, making this issue rather complex.[1-6] Using high-resolution transmission electron microscopy (TEM), Gu et al.[1] demonstrated hcp-structured epi-Co on GaAs and Mangan et al.[2] observed the coexistence of bcc and hcp phases. Idzerda et al.[3] confirmed the bcc structure of Co on GaAs(110) using extended x-ray absorption fine structure. Theoretical studies suggest that bcc Co is not a metastable phase but a forced structure originating from imperfections.[4, 5] Calculations show bulk bcc Co can have a magnetic moment as large as 1.7 \( \mu_B/\text{atom} \).[6] The tendency to form into bcc stacking, which doesn’t exist in nature, has also been found in epitaxial Ni thin films on GaAs. This was firstly demonstrated by Tang et al.[7] as early as 1986 by growing Ni on GaAs(001) at RT. The presence of bcc phase was observed up to 2.5 nm. This study was later on reproduced by X. M. Jiang et al.[8] who alternatively did the growth at 170 K and obtained a thicker bcc Ni, i.e. 3.5 nm. The bcc Ni/GaAs(100) as having a Curie temperature \( T_c \) of 456 K and a magnetic moment of 0.52 \( \mu_B/\text{atom} \), reveals a remarkably different electronic structure to that of fcc Ni and crucially a positive cubic anisotropy of \( +4.0 \times 10^5 \text{ergs/cm}^3 \), as opposed to \( -5.7 \times 10^4 \text{ergs/cm}^3 \) for the naturally occurring fcc Ni.

The interdiffusion between the FM and the SC atoms also play an important role in determining the magnetic properties of the ultrathin FM films. Theoretical calculations suggest that a bulk bcc Co can carry a magnetic moment as large as 1.7 \( \mu_B/\text{atom} \),[6, 9] while experimental reports are always below this value. By careful analyses of the RHEED patterns, Monchesky et al.[10] demonstrated a ferromagnetically dead layer associated with the formation of interfacial Co$_2$GaAs for Co thickness less than 3.4 monolayers (MLs) and an abrupt in-plane spin-reorientation transition reorients the magnetization along the [001] direction at 7 ML. It should be noted that all these boundaries discussed above are not absolute values but strongly depend on the specific sample deposition conditions, such as
the surface atomic configuration of the substrate and the growth temperature etc.. For example, passivating layers such as S and Sb have been used to reduce the chemical interaction at the Co/GaAs interface and the latter gives a factor of 2.3 enhancement of the magnetic moment compared to the film deposited on bare GaAs(110) substrate.[3] Characterized by x-ray photoelectron spectroscopy (XPS), the presence of the As peak in the 6-nm Ni film reveals the occurrence of As diffusion into the Ni layer destroying the magnetic properties of the fcc Ni film and leading to a 20% reduction of the magnetization compared to the bulk value.[11] In the study of the evolution of interface properties of the electrodeposited Ni film upon annealing, a significant increase of As out-diffusion has been observed for annealing temperatures up to 623 K accompanying a rise in the Schottky barrier height, which has been attributed to the Ni-Ga-As compound formation.[12]

The third reason is the reduced thickness. It is well known that FM materials follow the so-called island growth geometry at low coverage. In other words, FM atoms at low thicknesses, typically less than a few MLs, can be too diffused to intensively interact with one another. For example, many researchers have reported on high quality epitaxial growth of Fe on GaAs, among which there exist the long lasting debate over the presence of magnetic dead layer at the Fe/GaAs interface.[13] This detrimental effect used to be attributed to the formation of antiferromagnetic Fe$_2$As[14] and half-magnetized Fe$_2$Ga$_2$As$_x$ in the vicinity of the interface, until Xu et al.[15] demonstrated the evolution of the magnetic phase of Fe/GaAs corresponding to the growth morphology. This result was further confirmed with unambiguous x-ray magnetic circularly dichroism (XMCD) measurement of the Fe/GaAs(100) interface.[16]

Direct experimental demonstration of the magnetic state of epitaxial FM/SC interface down to the atomic scale remains a nontrivial task, even up to this day, partially due to the inaccessibility of the buried layer (referred to as FM$_2$ hereafter) between the upper layers (referred to as FM$_1$ hereafter) and the substrate. One classical method of resolving this problem is to engineer the FM$_1$/FM$_2$/SC superstructure, as shown in Figure 2.[16-18] Here, the FM$_2$ layers, usually with one monolayer thickness, are epitaxially deposited on the SC and then capped with a thick layer of FM$_1$ (≠ FM$_2$), which serves as the stabilizing layer. The thick FM$_1$ is chemically distinguishable but magnetically akin to the FM$_2$, providing it with a source of exchange interaction. Combined with the unique element selectivity of XMCD, this structure allows direct observation of the interfacial behavior of the bulk FM$_2$ on the SC. Applying this approach to two model FM/SC systems, namely Co/GaAs and Ni/GaAs, Liu et al.[18] observed a robust room temperature magnetization of the interfacial Co, whilst that of the interfacial Ni was strongly diminished down to 5 K due to strong hybridization of the Ni $d(e_g)$ and GaAs $sp^3$ states.
The validity of this method was confirmed by first-principles calculations, showing only small deviations (<0.02 and <0.07 $\mu_B$/atom for Co/GaAs and Ni/GaAs, respectively) compared to the real FM/SC interfaces. Their work has proved that the electronic structure and magnetic ground state of the interfacial FM$_2$ is not altered when the topmost FM$_2$ is replaced by FM$_1$ and that this model is applicable for probing both magnetically active and dead layers.

Figure 2. Demonstrate of the FM$_1$/FM$_2$/SC superstructure model. Upper row: Illustration of the FM$_1$/FM$_2$/SC structure (right) retrieving the FM$_2$/SC structure (left). Lower row: the magnetic moment of Co/GaAs and Ni/GaAs interfaces versus distance along the (100) direction. The dashed lines indicate the interfacial or the FM$_2$ region, where the magnetic ground state of the interfacial FM$_2$ is not altered when the topmost FM$_2$ is replaced by FM$_1$. [18]

3. Diluted Magnetic Semiconductor Thin Films

One of the most useful aspects of SCs resides in their capacity to be doped with impurities, by which the electrical properties of the SC can be tuned. This approach has been developed to introduce 3d metals such as Fe, Co, V and Cr into the non-magnetic SCs to make them magnetic, known as DMSs.[26] The concept behind it is that to transfer spin between similar materials would be a simpler task than over a metal-SC interface due to the retained control over band-gap engineering. The long established presence of spin filtering
effects in these SCs[27] and more recently the spontaneous[28, 29] or field controlled[30, 31] magnetic ordering add to their viability in this field. The early experimental efforts on the demonstration of DMSs started from II-VI (such as CdTe and ZnSe) in which the transition metal ions (such as Mn) are easy to be doped to high concentrations.[32] The fabrication of III–V DMSs, on the other hand, was limited mostly to (In,Mn)As,[28] (Ga,Mn)Sb,[33] and (Ga,As)Mn,[29, 34, 35] in which demonstrably carrier-mediated ferromagnetism already persists.

While DMSs may offer opportunities of easy integration with conventional SC-based devices, it is however a great challenge to improve the quality of DMS and in particular to enhance their magnetism.[35-43] With the thickness down to nanometer scale, these issues become even more sophisticated. For example, (Ga,As)Mn is a technological important material due to its potential use in short-range optical communications, however, whose highest $T_c$ up to now is no more than 200 K even after combining efforts of heavy Mn doping, nano-patterning, optimizing the growth conditions, and post-growth annealing.[34, 35, 37, 44] RT ferromagnetism has been predicted and demonstrated in oxide DMS and nitride-based DMS such as Co- and Mn-doped ZnO and Fe-doped GaN. However, debates still exist on whether the ferromagnetism obtained in these DMS systems is intrinsic or not, and whether the defects is responsible for the magnetic ordering.[38, 39]

In a magnetic bilayer system, the exchange coupling from a ferromagnetic layer can induce a spin polarization in the nonmagnetic layer or enhance the $T_c$ in the other magnetic layer with low ordering temperatures through proximity effect. By such approach, substantial increase of $T_c$ from 40 to 70 K due to the presence of a few monolayers of Fe atop (Ga,Mn)As was obtained by Song et al. in a lateral spin injection device.[40] The magnetic proximity effect persists to room temperature at the Fe/(Ga,Mn)As interfaces was reported by Maccherozzi et al.,[41, 42] who observed a significant induced magnetic order in the (Ga,Mn)As layer that extends over 2 nm, as shown in Figure 33. An antiparallel magnetic coupling between Fe and Mn, with ferromagnetic order in the (Ga,Mn)As layer was observed and high exchange bias up to 240 Oe was revealed in this system by Olejnik et al.[43] Altering the Fe induction layer with the high $T_c$ half metallic Heusler alloy Co$_2$FeAl, Nie et al. demonstrate that a 1.36 nm thick (Ga,Mn)As thin film remains ferromagnetically ordered up to 400 K. Unlike the antiferromagnetic coupling in Fe/(Ga,Mn)As system, these authors observed a parallel alignment between the Fe, Co and the Mn in the Co$_2$FeAl/(Ga,Mn)As system.

4. Magnetic Topological Insulators

As a class of matter with newly discovered eccentric electronic phase, the spin-orbit induced TIs have a rather short history but fast growing family.[45-47] Since they were first theorized in 2005[48] and experimentally produced in 2006,[49] TIs, with their ability to insulate on the inside and conduct on the outside, have presented new possibilities for the future spintronic engineering. Three-dimensional (3D) TIs feature novel phases of quantum matter characterized by sharp changes in electronic structure at their very surfaces, i.e. with insulating bulk band gap and gapless Dirac-like band dispersion surface state (SS). Unlike the different electronic properties of the surface and the bulk universally existing in all solids owing to the inevitable termination of periodic lattice structure when approaching the edges, TIs present a new class of nontrivial SS arising from the intrinsic strong spin-orbital coupling (SOC) and characterized by a Rashba spin texture.[50-52] These low-dimensional conducting states are immune to localization as long as the disorder potential is time-reversal-invariant and therefore have strong implications for the emerging technologies such as dissipationless spin transport and quantum computing.[53, 54] Breaking time-reversal-invariance by introducing magnetic perturbation, on the other hand, reveals a complex phenomenology associated with an excitation gap of the surface...
spectrum, resembling that of a massive Dirac fermion. [55, 56] Such a system with a tunable gap promises rich exotic topological phenomena and potentially allow purely electric control of the surface transport and magnetization. [45, 57, 58]

Two categories of route for introducing ferromagnetic order or breaking time-reverse symmetry (TRS) in TIs have been developed. One route is to dope the TI host with specific elements, by which ferromagnetism has been observed in Cr- and Mn-doped single crystals of Sb$_2$Te$_3$, [59-61] Fe-, and Mn-doped single crystals of Bi$_2$Te$_3$, [62, 63] and Mn- and Cr-doped thin films of Bi$_2$Se$_3$. [64, 65] However, for the electronic and magnetic ground state of the magnetically doped TIs, evidence from the experimental observations including magneto-transport measurements, [60] global magnetometry, [55] and core-level spectroscopies [66-68] are so far inconclusive. Magnetic studies on epitaxial, Cr-doped Bi$_2$Se$_3$ using superconducting quantum interference device - vibrating sample magnetometer magnetometry (SQUID-VSM) [64] and polarized neutron reflectometry (PNR) [68] universally reported a magnetic moment of no more than \( \sim 2 \) \( \mu_B \)/atom, remarkably lower than the Hund’s rule of 3 \( \mu_B \)/atom of substitutional Cr$^{3+}$ on Bi sites. According to the pioneering work by Haazen et al. [64] the magnetic moment of Bi$_{2-x}$Cr$_x$Se$_3$ decreases with increasing doping concentration and sharply drops beyond \( \sim 10\% \). This is well resembled by Liu et al. [69] using a combined approach of XMCD and density function theory (DFT) calculation, as summarized in Figure 4. These authors found a remarkable fraction of the (Cr$_{bi}$-Cr$_{ti}$)$^{3+}$ antiferromagnetic dimers in the Bi$_{2-x}$Cr$_x$Se$_3$ for 0.02 < x < 0.40, which was neglected in previous studies. Significant mismatch also exists in Mn- and Fe-doped Bi$_2$Se$_3$, who typically show global magnetic moments of \( \sim 1.5 \) \( \mu_B \)/atom and \( \sim 3\mu_B \)/atom, while their Hund’s rule prediction is 5 \( \mu_B \)/atom. It has been proposed that in magnetic TIs, ferromagnetic moments can be developed not only through the s-d exchange interaction such as in diluted magnetic semiconductors (DMSs), [34, 70-73] but also through the van Vleck mechanism, by which magnetic ions are directly coupled through the local valance electrons. [47] Both types of mechanism have been observed independently in Mn-doped Bi$_2$(TeSe)$_3$ [74] and Cr-doped (BiSb)$_2$Te$_3$ [75] thin films. Delicate technique like time-resolved angular-resolved photoemission spectroscopy (TR-ARPES) has been performed to distinguish bulk and surface electron-phonon coupling of the bare TI. [76] In the regard of magnetic TI, \( \beta \)-nuclear magnetic resonance (\( \beta \)-NMR) was very recently used to depth-profile the electronic wavefunctions at topological surfaces. [77]
Figure 4. A summary of the experimentally measured and the DFT-calculated dependence of (a) magnetic moment and (b) the fraction of the three predominant defects CrI$^{3+}$, CrBi$^{0}$, and (CrBi-CrI)$^{3+}$, as a function of the chemical potential of Cr ($\mu$Cr) in Bi$_2$CrSe$_3$ [69].

The other routine of making TIs magnetic is to engineer layered heterostructures, where the SS of TIs experience the exchange interaction from an adjacent ferro- or ferrimagnetic material. This route subsequently can be divided into two ways in terms of ferro- or FM and ferro- or ferri-magnetic insulator (FMI) induction. Pioneering theoretical work [78-80] suggests that suitable FMIs have the potential to achieve a strong and uniform exchange coupling in contact with TIs without significant spin-dependent random scattering of helical carriers on magnetic atoms. Progresses are made experimentally in FMI/TI heterostructures including GdN/Bi$_2$Se$_3$ by Kandala et al. [81] EuS/Bi$_2$Se$_3$ by Yang et al. [82] and Wei et al. [83] respectively, although the effect observed is limited to low temperature (< 22 K) due to the low $T_C$ of EuS. The interface magnetism of (anti-) FM/TI heterostructures, such as Fe/Bi$_2$Se$_3$ [56, 84, 85] Co/Bi$_2$Se$_3$ [85] and Cr/Bi$_2$Se$_3$ [86] has also been investigated. Remarkably, Vobornik et al. [87] demonstrated that long-range ferromagnetism up to RT can be induced in Bi$_2$Mn$_x$Te$_3$ by a deposited Fe overlayer, as shown in Figure 5. However, in the presence of a metallic layer, the nontrivial surface states of the TI can be significantly altered due to their hybridization with the bulk states of the (anti-) FM in contact. Besides, the metallic layer naturally short circuits the TI layer and therefore fundamentally restrict the device design. Using high-$T_C$ ferrimagnetic insulator, Liu et al. [89] demonstrated the magnetic proximity effect of Bi$_2$. 

and obtained a large (6.6 nm at 30 K) but fast decreasing penetration depth compared to that of ordinary DMSs. This could indicate a novel mechanism for the interaction between the ferromagnetic insulator and the nontrivial TIs surface and has strong implications for the TI-based dissipationless electronic devices, as it no longer limits the “proximity” to short range.

Figure 5. The antiferromagnetically coupled hysteresis loops of Mn and Fe, respectively, from the Fe/Bi$_2$Cr$_3$Se$_3$/Y$_3$Fe$_5$O$_{12}$ bilayer from 22 K to 273 K.[87]

5. Magnetic Graphene and Transition Metal Dichalcogenides

Since its successful synthesis by mechanical exfoliation from graphite in 2004, graphene has attracted enormous attention in the community of physics, chemistry and materials science.[90] As a prototypical two-dimensional quantum system, graphene displays a combination of exceptional properties including large charge carrier mobility, high thermal conductivity, strong mechanical strength, excellent optical characteristics, electrically
tuneable band gap, as well as the recently discovered long spin coherence length.[91-93]

The revolutionary nature of graphene makes it a prime candidate to become a key material for the proposed SFET, in which the generation and tuning of spin-polarized currents are prerequisites.[94-96] In pristine state, graphene exhibits no signs of conventional spin-polarization and so far no experimental signature shows a ferromagnetic phase of graphene. This gap is now filling up by combined efforts in multi-disciplinary research. While ideal graphene is non-magnetic, many of its related materials and nanostructures, either realized in practice or considered theoretically, have shown various scenarios of magnetism. Pioneering works reveal that spin origin in graphene are related to defect, vacancy, and edge state where topological frustration of the p-bonds occurs. This was first discussed by Son, Cohen and Louie, [97] who showed that external electric fields can induce half-metallicity – the coexistence of a metallic state for electrons with one spin orientation and an insulating state for electrons with the opposite spin orientation. In the zigzag graphene nano-ribbon (ZGNR), Enoki et al. [98] observed localized spins in nano-graphite domains of activated carbon fibers and attributed the origin to the zigzag edges as shown in Figure 6.

![Figure 6](image)

Figure 6. Scheme of electric-field-induced half-metallicity in ZGNR. (a) Electric field is applied across the nanoribbon, from left edge (spin-up, red arrows) to right edge (spin- down, blue arrows). (b) Schematic representation of the spin-resolved local density of states for the opposite edges at zero applied field. (c) Applied electric field breaks the symmetry for different spin types.[99]

Engineering FM/graphene heterojunction is one of the most effective avenues to realise spin injection into graphene and this was first achieved by Ohishi et al. into ZGNRs
Fascinating properties of spin transport phenomena have been presented in the Co/graphene system,[100, 101] though theoretical calculations show that the atomic magnetic moment of Co can be reduced by more than 50% when absorbed on graphene surface.[102] The magnetic moment of monolayer Fe is reduced but still sizable when epitaxially deposited on graphene, and this in turn induces a spin polarization in the carbon atoms.[103] The graphene-based FET has been demonstrated in back gated devices on highly doped Si,[104] and the conductance of the top surface of such structures can be modulated via gas exposure and top-back dual gates.[102] The spin valve effect was also successfully demonstrated in NiFe/graphene/NiFe vertical structures and the signal was enhanced when the number of graphene layers is doubled.[105] An inserted graphene sheet can drastically improve the spin-injection efficiency from a ferromagnet into silicon.[106] The interaction of graphene with FM surface plays a fundamental role in the related technological process, which has renewed the interest of FM/SC heterojunctions, although the binding mechanism of the FM/graphene interface is still far from a complete understanding.

Beyond graphene, the unique electronic and optical properties of TMDs are establishing them as the next hotspot in 2D materials research. Despite the plethora of reports on the electronic structure of the single layer TMDs it was only recently that their magnetic features have been investigated. So far VS$_2$ and VSe$_2$ are the only 2D materials with their magnetism confirmed in the pristine state.[99] For metal intercalated TMDs, Fe$_x$NbSe$_2$ and Cu$_x$NbSe$_2$ were proved to be magnetic.[107] In the case of MoS$_2$ the presence of magnetism was believed to be related to the defects (including structural defects and/or adatoms and/or impurities).[108] The substitution of a S atom by atoms of complete $d$ band (Pd and Au) was found not to lead to magnetic polarization except for a slight modification of the density of states near $E_F$.[109] On the other hand, substitution of a S atom by atoms with incomplete $d$ band atoms (Fe, Mn and V) was found to induce spin polarization and significant modification of the states near the band edges.[110] The adsorption of certain metallic adatoms on 2D MoS$_2$ can also incur magnetism.[109, 111]

Very recently the effect on TMD’s magnetism upon cation substitution with magnetic impurities has become a key subject of interest. Mishra et al.[112] investigated the long-range ferromagnetic ordering in fairly diluted Mn doped (less than 5%) MoS$_2$, MoSe$_2$, MoTe$_2$, and WS$_2$ within the density functional theory–spin polarized generalized gradient approximation and Hubbard- $U$ (SGGA+$U$) parametrization. Cheng et al. [113] studied the magnetism of the MoS$_2$ monolayer doped with Mn, Fe, Co, Zn, Cd, and Hg and found that the Fe and Co doping lead to antiferromagnetic ground states, while the doping with Mn, Zn, Cd, and Hg lead to ferromagnetic ground states. Ramasubramaniam and
Naveh[114] compared the results for the exchange coupling coefficient among Mn dopants in MoS$_2$. They found ferromagnetic coupling between Mn dopants and antiferromagnetic coupling between the Mn dopants and their first nearest neighbor S anions. The very first successful experimental demonstration of \textit{in situ} doping of monolayer TMD is the Mn-doped MoS$_2$ included in Figure 7, reported by Zhang \textit{et al.}[115] with the assistance of a graphene buffer layer on sapphire. Unlike the theoretical studies which have focused on doping of freestanding 2D materials, these authors show that the capacity of the incorporation of magnetic dopants in TMD is highly dependent on the choice of the substrate.

![Figure 7. Experimental demonstration of Mn-doped MoS$_2$. Left: TEM image of Mn-doped MoS$_2$. Right: Two-terminal conductance versus back gate voltage measurements indicating that Mn-doping leads to an increase in the density of states in the bandgap of the MoS$_2$ and thus lower saturation conductance.[115]](image)

6. \textbf{Summary and Outlook}

2D systems have become one of the most exciting new classes of materials due to the wealth of exceptional physical properties that occur when charge, spin and heat transport are confined to a plane. Their unique 2DEG-like behaviours not only enrich the world of low-dimensional physics, but also provide a platform for transformative technical innovations. In the pursuit for such goals, the intrinsic material properties (\textit{e.g.} mobility, anisotropy, conductivity \textit{etc.}) are important indicators and the artificially synthetized hybrid systems (\textit{e.g.} multilayers, hybrid systems, and nano-structures \textit{etc.}) are valuable models for studying spin-dependent phenomena and could potentially be used as actual components for an eventual spintronic device.
Among the four representative 2D systems reviewed in this article, FM thin films have the topmost advantages of spontaneous magnetization and usually high $T_c$. Their electronic and magnetic ground states have been intensively studied in the history, though dramatic alterations occur when it comes to the FM/SC interface. Using FM as spin filters also bring problems such as the well-known conductivity mismatch, based on the fact that a FM metal has a conductivity typically several orders of magnitude larger than that of a SC, which has limited the efficiency of spin injection. Interface engineering by means of improved epitaxial deposition, interface doping, and buffer layer insertion etc. may eliminate the undesired effects and further enhance the operation temperature of the FM/SC-based spintronic devices. By contrast, DMS thin films naturally avoid the difficulties of integration with conventional SC-based technologies; however great challenges remain to improve their crystallinity and in particular their $T_c$. Magnetic proximity effect is a promising pathway in this regard; and in this regard, not only many DMS thin films, but also the newly discovered TIs have shown their pronounced capacities with several high $T_c$ magnetic materials via proximity. The later even reveals an increasing penetration depth, which is expected to free the proximity effect from short-range limit. Future work to explore the tuning of the magnetization of TIs and its dependence on the band filling will be of both great fundamental interest and practical merits.

2D materials like graphene and TMDs carry the desired long spin lifetime as well as the outstanding mechanical and optical properties that FM, DMSs and TIs don’t have. It is rather unconventional to seek for magnetism from these Van der Waals materials, which were believed nonmagnetic. Nevertheless research into magnetic graphene and magnetic TMDs has rapidly taken off, though their magnetic signatures are so far fragile and limited to cryogenic temperatures. This is because the origin of spin polarization of these materials are usually defects, vacancies, edge states, impurities and/or via the proximity to an adjunct magnetic source etc.. Direct magnetic doping to high concentration and forming long-range magnetic ordering persisting up to RT are still major obstacles for magnetic graphene and TMDs. Investigations into the interplay between imbalanced spin states and the Dirac-like band dispersions will lead to experimental approaches to enhance the magnetism in 2D materials and can give rise to novel physical phenomena such as AQHE at RT.
