18 **Abstract**

19 Birnessite minerals are layer-type manganese oxides characterized by large surface areas,  
20 the presence of cation vacancy sites and varying amounts of structural and adsorbed Mn(III). In  
21 this study, we identify the conditions that favor trace metal adsorption on the edge surfaces of  
22 birnessite nanoparticles by using Ni as a probe ion for Ni K-edge extended X-ray absorption fine  
23 structure (EXAFS) spectroscopy and geometry optimizations based on density function theory  
24 (DFT). In  $\delta$ -MnO<sub>2</sub> nanoparticles free of Mn(II,III) at pH 6.6, Ni was adsorbed primarily at  
25 vacancy sites, with a minor fraction of Ni present as a double-edge sharing (DES) or a double-  
26 corner sharing (DCS) complex at surface loadings exceeding the vacancy content. In Mn(III)-  
27 rich  $\delta$ -MnO<sub>2</sub> nanoparticles, about 80 % of the adsorbed Ni formed a mixture of DES and DCS  
28 complexes at particle edges in samples with loadings ranging from 0.01 to 0.08 mol Ni mol<sup>-1</sup>  
29 Mn, with only a small fraction of vacancy sites available to adsorb Ni. The presence of Mn(III)  
30 at the nanoparticle edges also changed the architecture of the DES complex, causing the Ni  
31 octahedra to adsorb onto the cavity formed between two Mn(III) octahedra at the particle edges.  
32 The EXAFS-derived Ni-Mn interatomic distances of 3.01 – 3.05 Å for this “flipped” Ni-DES  
33 complex were in excellent agreement with those obtained by DFT geometry optimization. Edge  
34 surfaces on birnessite nanoparticles have a lower affinity for trace metals than vacancy sites, but  
35 have a moderate sorption capacity (ca. 0.14 mol Ni mol<sup>-1</sup> Mn at vacancies vs. 0.06 mol Ni mol<sup>-1</sup>  
36 Mn at edge surfaces). Finally, although Mn(III) increases the relative proportion of Ni adsorbed  
37 at particle edges by blocking sorption sites on the basal surface, the overall sorption capacity of  
38 the mineral diminishes significantly.

39

## 40 1. INTRODUCTION

41 Birnessite (layer-type  $\text{MnO}_2$ ) minerals undergo strong adsorption reactions with trace  
42 metals due to their large specific surface area and negative surface charge (Post, 1999; Tebo et  
43 al., 2004). Cation vacancies in the  $\text{MnO}_2$  sheet, Mn(III) substitution for Mn(IV), and  
44 undercoordinated oxygen atoms at particle edges (Bargar et al., 2009; Lanson et al., 2002b;  
45 Manceau et al., 2002; Manceau et al., 2013; Villalobos et al., 2006; Zhu et al., 2012) lead to  
46 various surface complex configurations for trace metals, as illustrated in **Fig. 1a – d**. Studies on  
47 the mechanisms of trace metal sorption by birnessite have focused on the reactivity of the  
48 vacancy sites (e.g. Drits et al., 2002; Lanson et al., 2002b; Manceau et al., 2002; Manceau et al.,  
49 2007; Peacock, 2009; Peacock and Sherman, 2007; Peña et al., 2010; Toner et al., 2006), with  
50 significantly fewer studies addressing the reactivity of particle edges (Kwon et al., 2010;  
51 Takahashi et al., 2007; Villalobos et al., 2005; Villalobos et al., 2014; Wang et al., 2012).

52 Birnessite particles occur typically as stacked sheets that extend only a few nanometers  
53 along the sheet-stacking direction (ca. 1 - 4 nm) and in the *ab* plane (ca. 2 – 10 nm) (Bargar et  
54 al., 2009; Lanson et al., 2008; Manceau et al., 2013; Villalobos et al., 2006). Because the  
55 proportion of sorption sites at particle edges increases with increasing specific surface area, the  
56 edge surfaces of these nanoparticles can contribute significantly to trace metal sorption.  
57 Villalobos et al. (2005) found a linear correlation between Pb surface excess and specific surface  
58 area, with an analysis of extended X-ray absorption fine structure (EXAFS) spectra indicating  
59 that 50 – 75 % of adsorbed Pb was located at particle edges.

60 The presence of Mn(III) also may influence the extent to which particle edges participate  
61 in trace metal sorption reactions. Recent structural models for  $\delta\text{-MnO}_2$ , a synthetic analog of

62 natural birnessite, include 0.05 to 0.30 mol Mn(III) mol<sup>-1</sup> Mn incorporated into the MnO<sub>2</sub> sheet  
63 or adsorbed above and below vacancy sites (Grangeon et al., 2008; Manceau et al., 2013; Zhu et  
64 al., 2012). Based on wet chemistry data, Wang et al. (2012) suggested that the relative  
65 contribution of edge sites to trace metal sorption increased as the Mn(III) content increased. The  
66 adsorption of Mn(III) at vacancy sites could render these sites less available to adsorb other  
67 metals, thus forcing increased trace metal sorption at particle edges. Furthermore, the presence of  
68 Mn(III) may influence the structural parameters of surface complexes on birnessite edge sites  
69 because the radius of Mn(III) (0.645 Å) is larger than that of Mn(IV) (0.53 Å).

70 Metals adsorbed on the edge surfaces of hexagonal birnessite have been reported to  
71 exhibit two coordination geometries: double-corner-sharing (DCS, **Fig. 1c**) and double-edge-  
72 sharing (DES, **Fig. 1d**). Both DCS and DES surface complexes have been proposed for Pb based  
73 on EXAFS spectroscopy (Takahashi et al., 2007; Villalobos et al., 2005). However, geometry  
74 optimizations based on density functional theory (DFT) (Kwon et al., 2010) show that DES is the  
75 preferred coordination for Pb, but the protonation of the mineral surface and the hydration state  
76 of the adsorbing metal cation can influence the adsorbate structure. For Ni sorption on hexagonal  
77 birnessite, only the DCS species has been reported (Manceau et al., 2007; Yin et al., 2012). The  
78 Ni-DCS species was inferred from a decrease in the number of Mn neighbors near 3.5 Å, the  
79 interatomic distance diagnostic of triple-corner-sharing surface complexes at vacancy sites (TCS,  
80 **Fig. 1a**). Overlap in the metal-Mn interatomic distance of DCS and TCS complexes has been  
81 observed for geometry-optimized Pb surface complexes (Kwon et al., 2010). If structural  
82 parameters for surface complexes at particle edges overlap with those for surface complexes at  
83 vacancy sites, it becomes difficult to assign the coordination geometry based on interatomic  
84 distances alone.

85           In the current study, we aim to clarify the mechanisms of trace metal sorption at particle  
86 edges on hexagonal birnessite. Of the trace metals of interest, including Fe, Co, Ni, Cu, Zn and  
87 Pb, only Ni is both redox-inactive and shows only symmetric octahedral coordination. These  
88 chemical properties facilitate the interpretation of spectroscopic data, thus making Ni the probe  
89 metal of choice for this study. We follow a synergistic experimental-computational approach that  
90 combines chemical measurements, EXAFS spectroscopy, and DFT geometry optimizations to  
91 investigate the mechanisms of Ni sorption by  $\delta$ -MnO<sub>2</sub>, a Mn(III)-rich  $\delta$ -MnO<sub>2</sub>, and triclinic  
92 birnessite at pH 6.6. The large specific surface area of  $\delta$ -MnO<sub>2</sub> provides ample edge surfaces for  
93 metal sorption, whereas the Mn(III)-rich  $\delta$ -MnO<sub>2</sub> sample allowed us to examine the role of  
94 Mn(III) without a major change in specific surface area, unlike previous studies (Wang et al.,  
95 2012; Villalobos et al., 2014). In addition, using triclinic birnessite (TcBi) as a sorbent, we could  
96 compare the structure of Ni surface complexes in a Mn(III)-rich birnessite which has no vacancy  
97 sites (Lanson et al., 2002a). We used EXAFS spectroscopy to probe the average bonding  
98 environment of Ni and estimate its distribution between different surface sites. The DFT  
99 calculations allowed us to determine the structural parameters for variety of surface complexes at  
100 the edges and to investigate the effects of protonation and Mn(III) on their structural parameters,  
101 which in turn helped to constrain our interpretation of the Ni K-edge EXAFS spectra.

102

## 103 **2. MATERIALS AND METHODS**

### 104 **2.1. Materials**

105           All solutions were prepared using ultrapure water with a resistivity of 18.2 M $\Omega$ ·cm  
106 (LaboStar, Siemens) and A.C.S. reagent-grade chemicals. The synthesis and characterization of

107 the  $\delta$ -MnO<sub>2</sub> powder used in this study is described elsewhere (Duckworth and Sposito, 2007).  
108 Synthetic  $\delta$ -MnO<sub>2</sub> may have varying amounts of lower-valent Mn in its structure, resulting in an  
109 average manganese oxidation number (AMON) < 4.0 that can arise from synthesis conditions  
110 (Wang et al., 2012), solution pH (Manceau et al., 2013), or aging of the mineral in aqueous  
111 suspension (Villalobos et al., 2003). In this study, we equilibrated  $\delta$ -MnO<sub>2</sub> (AMON = 4.01  $\pm$   
112 0.05) in a 10 mM NaCl and 10 mM HEPES buffer solution to produce a Mn(III)-rich  $\delta$ -MnO<sub>2</sub>  
113 with AMON = 3.65  $\pm$  0.05. The fractions of Mn(II) and Mn(III) in the solid were determined to  
114 be 2  $\pm$  1 % and 34  $\pm$  1 %, respectively, using pyrophosphate extractions (see Electronic Annex).  
115 Although HEPES belongs to the Good's buffers that are considered inert and thus widely used to  
116 control pH (Good et al., 1966), the piperazine-ring group in the HEPES molecule can act as an  
117 electron donor to Mn(IV) (Buchholz et al., 2011; Grady et al., 1988; Kirsch et al., 1998; Zhao  
118 and Chasteen, 2006) and lead to the accumulation of Mn(III) in  $\delta$ -MnO<sub>2</sub>. The structural  
119 characteristics of this modified  $\delta$ -MnO<sub>2</sub>, which we denote as Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub>, are discussed in the  
120 **Electronic Annex**. Triclinic birnessite (TcBi) was synthesized by oxidation of Mn<sup>2+</sup> at pH 8  
121 (Drits et al., 1997; Giovanoli et al., 1970), since at this alkaline pH, no vacancy sites are  
122 expected to form (Drits et al., 1997; Silvester et al., 1997). The properties of our unmodified Mn  
123 oxide samples (**Table 1**) compare well with available literature data (Drits et al., 1997;  
124 Villalobos et al., 2003; Yang and Wang, 2001). The Mn oxides were stored as dry powders at 4 °  
125 C or -20 °C.

## 126 **2.2. Sorption experiments**

127 Sorption experiments with  $\delta$ -MnO<sub>2</sub> and Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub> were conducted at pH 6.6, with  
128 pH maintained constant using a pH STAT (Metrohm) or HEPES buffer (Fisher Scientific). The

129  $\delta$ -MnO<sub>2</sub> powder was ground using an agate mortar and pestle and resuspended in either 10 mM  
130 NaCl (for sorption experiments on  $\delta$ -MnO<sub>2</sub>) or 10 mM NaCl and 10 mM HEPES buffer (for  
131 sorption experiments on Mn<sup>III</sup> $\delta$ -MnO<sub>2</sub>) to achieve a total Mn concentration of 5.7 mM. The  
132 mineral suspension was sonicated for one hour (Bransonic 3510 Ultrasonic Cleaner). For pH-  
133 STAT experiments ( $\delta$ -MnO<sub>2</sub>), after sonication, 80 mL of the suspension were transferred to a  
134 titration vessel on a stir plate and the pH was adjusted to 6.6 by addition of 50 mM HCl. The  
135 mineral suspension was equilibrated at pH 6.6 for 30 – 60 min, after which an aliquot of 40 mM  
136 NiCl<sub>2</sub> was added to achieve an initial Ni concentration between 0 and 1400  $\mu$ M. In all  
137 experiments, the Ni concentrations were below the solubility limit of  $\alpha$ -Ni(OH)<sub>2</sub>. After Ni  
138 addition, the suspension pH dropped to about pH 5.5; the pH was re-adjusted using 50 mM  
139 NaOH and maintained at pH 6.6 for 48 h. For the HEPES-buffered experiments (Mn<sup>III</sup> $\delta$ -MnO<sub>2</sub>),  
140 after sonication, 12 mL of the mineral suspension was transferred from a stock suspension under  
141 vigorous stirring to 15-mL polypropylene Falcon tubes. An aliquot of a 10 or 40 mM NiCl<sub>2</sub>  
142 solution was added to each of 30 tubes to achieve initial Ni concentrations between 0 and 1400  
143  $\mu$ M. All tubes were placed on an end-over-end shaker (Enviro-Genie, Scientific Industries, Inc.)  
144 for 48 h at 35 rpm. Finally, to ensure that HEPES did not modify the sorption of Ni by Mn<sup>III</sup> $\delta$ -  
145 MnO<sub>2</sub>, we conducted additional control experiments using Mn<sup>III</sup> $\delta$ -MnO<sub>2</sub> without HEPES in the  
146 background electrolyte. To initiate these experiments,  $\delta$ -MnO<sub>2</sub> was equilibrated with HEPES for  
147 one hour. The Mn<sup>III</sup> $\delta$ -MnO<sub>2</sub> solids were collected by filtration and resuspended in 10 mM NaCl;  
148 the suspension pH was adjusted to 6.6 and maintained constant on a pH-STAT during the Ni  
149 sorption reaction.

150           After 48 h of equilibration, two samples were collected to determine total and aqueous  
151 metal concentrations. One milliliter of the suspension was digested with 9 mL of 1.5 % HNO<sub>3</sub>

152 and 10 mM oxalic acid for analysis of total Mn and Ni concentrations ( $c_{\text{MnTOT}}$  and  $c_{\text{NiTOT}}$ ). The  
153 remaining slurry was filtered through a 0.22  $\mu\text{m}$  syringe filter (Millipore). The pH of the filtrate  
154 was measured using an Orion A111 pH meter (ThermoScientific) and a semi-micro combination  
155 glass pH electrode (Orion Ross, ThermoScientific). The filtrate was then acidified with  $\text{HNO}_3$  for  
156 analysis of aqueous Mn and Ni concentrations ( $c_{\text{Mn}}$  and  $c_{\text{Ni}}$ ). The empty test tubes were rinsed  
157 first with 5 - 10 mL ultrapure water and then with 5 mL of 1.5 %  $\text{HNO}_3$  and 10 mM oxalic acid.  
158 Both rinse solutions were analyzed for Ni and Mn concentrations to test whether any Ni or Mn  
159 was retained on the tube walls.

160 Metal concentrations were measured by inductively coupled plasma optical emission  
161 spectrometry (ICP-OES, Perkin-Elmer Optima 8300) in triplicate using one to three emission  
162 lines per element. Nine standard solutions in the range 0.5 to 500  $\mu\text{M}$  were prepared from 1000  
163 mg/L Perkin-Elmer single element standards. Measured intensities were corrected relative to the  
164 intensity obtained from a 50 ppm Sc internal standard. The surface excess of Ni ( $q$ ) was  
165 calculated as  $(c_{\text{NiTOT}} - c_{\text{Ni}})/(c_{\text{MnTOT}} - c_{\text{Mn}})$  in units of  $\text{mol Ni mol}^{-1} \text{Mn}$  (Peña et al., 2010). Control  
166 experiments showed that at most 2 – 4 % of the total Mn was bound to test tube walls; surface  
167 excess values of Ni in this fraction corresponded to the Ni surface excess values in the slurry.  
168 Thus, we concluded that this small loss of Mn oxide to the tube walls did not influence any  
169 trends in our results. Finally, identical surface excess values were measured with and without  
170 HEPES in the background electrolyte (data not shown).

### 171 **2.3. Average Mn oxidation number determination**

172 Average Mn oxidation numbers (AMON) were determined by a three-step potentiometric  
173 titration (Metrohm 888 Titrando) that yields a concentration-independent measure of average Mn

174 oxidation number (Grangeon et al., 2012; Lingane and Karplus, 1946; Vetter and Jaeger, 1966).  
175 In Step 1, a 0.02 M Mohr's salt  $[(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2]$  solution is titrated with 0.02 M  $\text{KMnO}_4$ . In  
176 Step 2, Step 1 is repeated after reductive dissolution of the Mn oxide in a second aliquot of the  
177 Mohr's salt solution, where the volumes of Mohr's salt solution in Steps 1 and 2 must be  
178 identical. The moles of Fe(II) consumed by Mn(IV,III) reduction to Mn(II) are determined by  
179 difference of the  $\text{KMnO}_4$  volumes used in Steps 1 and 2. In Step 3, the total moles of Mn(II) is  
180 determined by back-titration of the solution obtained at the end of Step 2 using 0.02 M  $\text{KMnO}_4$   
181 in excess Na pyrophosphate (PP) to trap Mn as Mn(III)-PP.

182 Samples for AMON determination were obtained by filtration. About 37 mL of the  
183 mineral suspension (See **Section 2.2**) were passed through a 0.45  $\mu\text{m}$  filter membrane  
184 (Millipore). The solid was washed with 30 mL of ultrapure water to remove any entrained ions.  
185 The filter membrane was transferred into a titration flask with 40 mL of 0.02 M Mohr's salt  
186 solution. For unreacted Mn oxide powders ( $\delta\text{-MnO}_2$  and TcBi), 40 mg mineral were dissolved in  
187 Mohr's salt solution. The AMON values in Table 1 are reported as the mean and standard  
188 deviation of triplicate measurements; the standard deviations ranged from  $\pm 0.04$  to  $\pm 0.05$ , which  
189 is consistent with the uncertainties reported previously for this method (Grangeon et al., 2012).  
190 The AMON values of unreacted (dry) and wet  $\delta\text{-MnO}_2$  were both close to 4.0, indicating that  
191 neither the filter membrane nor residual water influenced the determination of the AMON.

#### 192 **2.4. X-ray absorption spectroscopy**

193 Samples used for XAS, prepared as described in **Section 2.2**, are listed in **Table 2**. Nickel  
194 surface loadings were selected to span the 6 to 11 % (mol vacancy  $\text{mol}^{-1}$  Mn) range in vacancy  
195 content reported for  $\delta\text{-MnO}_2$  (Manceau et al., 2013; Villalobos et al., 2003). For all samples

196 investigated by XAS, an aliquot of the mineral suspension was collected onto a Millipore filter  
197 membrane (ca. 4 mg cm<sup>-2</sup>). Filter membranes were attached to an Al sample holder and covered  
198 with Kapton tape.

199 X-ray absorption spectra were collected at beam lines 4-1 and 11-2 (beam energy 3 GeV,  
200 current 450 – 500 mA) of the Stanford Synchrotron Radiation Lightsource using a Si(220)  $\phi =$   
201 90° double crystal monochromator. The vertical slit size was set to 1 mm. The monochromator  
202 energy was calibrated using a Ni foil by setting the first inflection point in the first derivative to  
203 8333 eV. The incident beam was detuned to 70 % at 10 keV to minimize higher-order  
204 harmonics. Sample holders were positioned at a 45° angle to the incident beam. Nickel K-edge  
205 spectra were collected in fluorescence mode using a 30-element Ge detector or Lytle detector  
206 filled with Ar gas and equipped with soller slits and a Co(III) foil as fluorescent filter. All X-ray  
207 absorption spectra were acquired at 77 K (liquid nitrogen cryostat), with three to seven scans  
208 collected per sample.

209 Data reduction and analysis of X-ray absorption spectra were performed in SIXPACK  
210 (Webb, 2005), which is built on the IFEFFIT engine (Newville, 2001). Replicate scans were  
211 aligned to a common energy scale and averaged. The averaged X-ray absorption spectra were  
212 background-subtracted and normalized by fitting the pre-edge region using a Gaussian function  
213 and the post-edge region using a quadratic function, with  $E_0 = 8347$  eV,  $R_{bkg} = 1.0$  Å, no clamps,  
214  $k$ -weight = 3. The normalized  $k^3$ -weighted EXAFS spectra were Fourier-transformed over a  $k$ -  
215 range of 3 – 11.6 Å<sup>-1</sup> using a Kaiser-Bessel apodization window with  $dk = 3$  Å<sup>-1</sup>.

216 Nickel K-edge EXAFS spectra were fitted in  $R$ -space to determine structural parameters  
217 for Ni surface complexes. Single- and multiple-scattering paths used for shell-by-shell fitting

218 were created using the FEFF6L code (Rehr et al., 1991). Crystal Maker (version 2.1.5,  
219 CrystalMaker Software Ltd.) was used to visualize different Ni coordination environments and  
220 obtain the atomic coordinates for the FEFF input files. The Ni-MnO<sub>2</sub> clusters were based on the  
221 crystal structure of hexagonal birnessite (Lanson et al., 2002a). The amplitude reduction factor  
222 ( $S_0^2$ ) was 0.96 in all fits (Peña et al., 2010). All interatomic distances ( $R$ ) were floated, while  
223 different fitting constraints were applied to determine coordination numbers ( $CNs$ ) and Debye-  
224 Waller factors ( $\sigma^2$ ).

225 In general, the EXAFS spectra were fit between 1 and 3.5 Å using three shells: Ni-O, Ni-  
226 Mn<sup>ES</sup>, and Ni-Mn<sup>CS</sup>. We used Ni-ES to denote any edge-sharing Ni surface complex (i.e., Ni  
227 incorporated at the vacancies [Ni-INC] and at the edges [Ni-DES]; **Figs. 1b and 1d**) and Ni-CS  
228 to denote any corner-sharing complex (i.e., Ni-TCS at the vacancies and Ni-DCS at the edges;  
229 **Figs. 1a and 1c**) because the structural parameters for surface complexes at particle edges may  
230 overlap with those for surface complexes at vacancy sites. To avoid *a priori* assignments of  
231 coordination geometries, we performed various fits with the  $CN$  of each Ni-Mn shell fixed to  
232 values between 2 and 6 under the assumptions that Ni adsorbed at particle edges has two Mn  
233 neighbors ( $CN = 2$ ), Ni adsorbed at a vacancy site has six Mn neighbors ( $CN = 6$ ), and Ni  
234 adsorbed in equal proportions between edges and vacancy sites displays an average  $CN = 4$   
235 (**Tables EA1, EA2**). Then, to estimate the fraction of Ni in CS versus ES configurations, we  
236 defined the amplitudes ( $A$ ) of the ES and CS Ni-Mn shells as  $CN * f$  and  $CN * (1 - f)$ , where the  
237  $CNs$  were constrained to varying values and  $f$  represents a species abundance scaling parameter.  
238 Finally, the  $\sigma^2$  values of the ES and CS shells were linked to each other (Peña et al., 2010) in fits  
239 to  $\delta$ -MnO<sub>2</sub> samples, but were both allowed to vary in fits to Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub> samples, which  
240 contained significant proportions of Mn(III) in the structure. Due to large difference in the ionic

241 radii of Mn(III) or Mn(IV) atoms (i.e. 0.645 and 0.53 Å, respectively), the  $\sigma^2$  values of the  
242 metal-Mn shells in the CS and ES complexes may differ significantly depending on metal  
243 coordination to Mn(III) or Mn(IV).

244 The fitting routine described above resulted in a large number of fits. In order to  
245 determine which fits were most plausible, we evaluated 1) whether the amplitudes of the Ni-Mn  
246 shells were consistent with a high or low number of Mn neighbors; 2) how well the  $\sigma^2$  value  
247 compared to values reported in the literature; and 3) the probability ( $\alpha'$ ) that a fit with R-factor  
248  $R_i$  represented a statistically better fit (> 60 %) than the fit with the lowest R-factor, following  
249 the Hamilton test (Calvin, 2013; Downward et al., 2006).

## 250 2.5. Geometry optimizations

251 Model Ni surface complexes for geometry optimization were constructed using a 1 nm  
252 nanodisk consisting of seven Mn(IV) octahedra (**Fig. 2**). For DCS species, Ni was initially bound  
253 to two singly-coordinated O ( $O_{1Mn}$ ) at the nanodisk lateral edge and four H<sub>2</sub>O molecules to  
254 achieve a coordination number of six. For DES species, Ni was initially bound either to one  
255 doubly-coordinated O ( $O_{2Mn}$ ) or one triply-coordinated O ( $O_{3Mn}$ ) along with two singly-  
256 coordinated O ( $O_{1Mn}$ ) and three H<sub>2</sub>O molecules to achieve a coordination number of six (e.g.,  
257  $DES_{O_{2Mn}}$  or  $DES_{O_{3Mn}}$ ). We also geometry optimized an edge-sharing species wherein Ni binds to  
258 three Mn octahedra via two singly- and two doubly-coordinated O (ES in **Fig. 2**). Dangling Mn-  
259 O bonds at particle edges were charge-balanced with one or two protons, yielding surface Mn-  
260 OH or Mn-OH<sub>2</sub> and an overall model structural formula,  $Mn_7NiO_xH_y$  ( $x = 27 - 28$ ,  $y = 24 - 26$ ),  
261 depending on surface complex type. Based on Pauling's second rule and magnetic moment

262 calculations (Kwon et al., 2010), the bridging  $O_{1Mn}$  between Mn and Ni is protonated (i.e. Mn-  
263 OH-Ni) (**Fig. 2**).

264 To investigate the effect of Mn(III) on the structural parameters of Ni-DES complexes,  
265 we replaced one or two Mn(IV) octahedra at the nanodisk edge with Mn(III) and geometry-  
266 optimized the structures,  $DES_{O2Mn}^{1Mn(III)}$ ,  $DES_{O3Mn}^{1Mn(III)}$ , and  $DES_{O3Mn}^{2Mn(III)}$ . When both Mn(IV) octahedra  
267 were replaced with Mn(III) octahedra to form  $DES_{O2Mn}^{2Mn(III)}$ , we were unable to obtain a stable  
268 geometry-optimized structure because Mn(III) transformed to a different oxidation state, as  
269 indicated by the calculated magnetic moment size. Thus we considered the  $DES_{O2Mn}^{2Mn(III)}$  species  
270 unstable.

271 Model Ni-MnO<sub>2</sub> structures were geometry-optimized using CASTEP, a planewave  
272 periodic DFT code (Clark et al., 2005) with the spin-polarized generalized gradient  
273 approximation functional GGA/PBE (Perdew et al., 1996) and ultrasoft pseudopotentials  
274 (Vanderbilt, 1990). The kinetic energy cutoff was 500 eV. To minimize spurious interactions  
275 between structural models of periodic cells, a sufficiently large simulation cell size of 20 Å x 20  
276 Å x 16 Å was used so that the model converged well with respect to structural parameters (Kwon  
277 et al., 2010). Geometry optimizations were carried out at one *k*-point at (0.0, 0.0, 0.0) under the  
278 BFGS procedure (Pfrommer et al., 1997) by relaxing all atoms of the surface complex in the  
279 fixed periodic cell. The energy tolerance was  $5 \times 10^{-6}$  eV/atom. The maximum tolerance for  
280 force and atom displacement along any Cartesian component was 0.03 eV/Å and 0.001 Å,  
281 respectively. The magnetic ordering was ferromagnetic among Mn ions but antiferromagnetic  
282 between Ni and Mn ions. The geometry-optimized structures in **Fig. 2** were visualized using the  
283 VESTA software (Momma and Izumi, 2011).

284 In geometry optimizations of the Mn(III)-rich nanodisk, we used the DFT + U formalism  
285 which adds the on-site coulomb interaction  $U$ , a Hubbard term, to the DFT total energy because  
286 standard DFT tends to over-delocalize the  $3d$  electrons in Mn oxides (Anisimov et al., 1997;  
287 Franchini et al., 2007; Rollmann et al., 2004). In CASTEP, the DFT + U formalism is  
288 implemented with a rotationally-invariant model (Cococcioni and de Gironcoli, 2005; Dudarev et  
289 al., 1998), which uses an effective Hubbard term ( $U_{eff} = U - J$ , where  $J$  is an intra-exchange  
290 term). We used  $U_{eff} = 2.5$  eV only for the  $3d$  orbitals of Mn(III) in the nanodisk. The calculated  
291 magnetic moment of Mn(III) was  $4.1 \mu_B$  ( $\mu_B$  is the Bohr magneton) while that of Mn(IV) was  $2.9$   
292  $- 3.0 \mu_B$ . The choice of  $U_{eff} = 2.5$  eV was validated based on the Mn- $3s$  exchange splitting energy  
293 ( $\Delta E_{3s}$ ), which correlates strongly with the Mn oxidation state (Oh et al., 1992). For example,  
294  $\Delta E_{3s}$  for Mn(IV) is 3.3 eV in the Mn(IV) nanodisk, while that for Mn(III) in LiMn(III)O<sub>2</sub> and  
295 PbMn(III)O<sub>2</sub>OH (quenselite) is 4.7 – 4.8 eV (Kwon et al., 2010). In the Mn(III)-rich nanodisk,  
296  $\Delta E_{3s}$  for Mn(III) was 5.0 eV, very close to the values for LiMn(III)O<sub>2</sub> and PbMn(III)O<sub>2</sub>OH.

### 297 3. RESULTS

#### 298 3.1. Nickel sorption isotherms

299 Nickel sorption isotherms for  $\delta$ -MnO<sub>2</sub> and Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub> at pH 6.6 are shown in **Fig. 3**.  
300 Sorption by  $\delta$ -MnO<sub>2</sub> followed an H-type isotherm, whereas for Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub> it followed an L-  
301 type isotherm (Sposito, 2008). For these latter Ni sorption data, a maximum surface excess equal  
302 to  $0.14 \pm 0.05$  mol Ni mol<sup>-1</sup> Mn was estimated from a plot of the distribution coefficient ( $K_d = q /$   
303  $c$ ) against surface excess ( $q$ ) (Sposito, 2008).

304 In Ni sorption experiments with  $\delta$ -MnO<sub>2</sub>, no aqueous Mn(II) was detected at the end of  
305 the sorption reaction and no change was measured in the AMON value of the solid phase (**Table**

306 2). By contrast, Ni sorption by  $\text{Mn}^{\text{III}}_{\delta}\text{-MnO}_2$  was accompanied by the accumulation of Mn(II)  
307 in solution (**Fig. EA4**). At loadings below  $0.04 \text{ mol Ni mol}^{-1} \text{ Mn}$ , only  $4 - 5 \text{ }\mu\text{M}$  Mn was  
308 released in solution. As the Ni loading increased from  $0.04$  to  $0.13 \text{ mol Ni mol}^{-1} \text{ Mn}$ , Mn(II) in  
309 solution increased linearly, reaching a maximum of  $3.5 \%$  of the total Mn concentration (**Fig.**  
310 **EA4**). The amounts of Mn(II) measured in solution correspond to an increase in the AMON of  
311 the solid phase by  $0.04 - 0.08$ , which is in agreement with the increase in measured AMON of  
312  $3.68$  to  $3.73$  as the Ni loading increased from  $0.01$  to  $0.08 \text{ mol Ni mol}^{-1} \text{ Mn}$  (**Table 2**). In  
313 addition, the amount of Mn(II) released to the aqueous phase upon Ni sorption is consistent with  
314 the amount of Mn(II) ( $2 \pm 1 \%$ ) initially sorbed at the surface of  $\text{Mn}^{\text{III}}_{\delta}\text{-MnO}_2$ . The linear  
315 relationship between the amounts of sorbed Ni and Mn(II) released at Ni surface loadings  $> 0.04$   
316  $\text{mol Ni mol}^{-1} \text{ Mn}$  (**Fig. EA4**) suggests that Ni and Mn(II) compete for the same surface sites  
317 (Murray, 1975; Peña et al., 2010).

### 318 3.2. Ni K-edge EXAFS spectra

#### 319 3.2.1. Coordination environment of Ni sorbed by $\delta\text{-MnO}_2$

320 Nickel K-edge EXAFS spectra and the corresponding Fourier transforms for  $\delta\text{-MnO}_2$   
321 equilibrated with Ni are presented in **Fig. 4**. The Fourier transforms show three dominant peaks  
322 at  $1.6$ ,  $2.4$ , and  $3.1 \text{ }\text{\AA}$  ( $R + dR$ ), representing Ni-O, Ni-Mn, and Ni-Mn shells, respectively. The  
323 peak at  $2.4 \text{ }\text{\AA}$  ( $R + dR$ ) is usually assigned to the first Ni-Mn shell for the Ni-INC species, while  
324 the peak at  $3.1 \text{ }\text{\AA}$  ( $R + dR$ ) is usually assigned to the first Ni-Mn shell for the Ni-TCS species  
325 (Manceau et al., 2007; Peacock and Sherman, 2007; Peña et al., 2010). In sample Ni 0.05, the  
326 amplitude of the CS shell was comparable to the amplitude of the Ni-Mn shell in samples with  
327 Ni sorbed dominantly at vacancy sites (Peña et al., 2010), while in sample Ni 0.18, the amplitude

328 of the CS shell was reduced by about 40 %. Thus, in our shell-by-shell fits (**Table EA1**) we  
329 excluded the possibility of a significant contribution from DCS species (low CNs) in Ni 0.05 and  
330 TCS species (high CNs) in Ni 0.18 (Manceau et al., 2007; Peña et al., 2010; Zhu et al., 2010b).  
331 All shell-by-shell fits returned a Ni-Mn<sup>ES</sup> distance of 2.84 – 2.91 ( $\pm 0.01$ ) Å and a Ni-Mn<sup>CS</sup>  
332 distance of  $3.47 \pm 0.01$  Å (Table 3). At low loadings (Ni 0.05), the best fits were obtained when  
333 the CN of the Ni-Mn<sup>CS</sup> and Ni-Mn<sup>ES</sup> shells were set equal to 6. At high loadings (Ni 0.18),  
334 statistically-similar fit results were obtained when the CN of the Ni-Mn<sup>CS</sup> shell was set equal to 5  
335 or 6 and the CN of the Ni-Mn<sup>ES</sup> shell was set equal to values between 3 and 6 (**Table EA1**).

336 In **Table 3** we report the fitting parameters for Ni 0.05 for the scenario in which Ni binds  
337 at vacancy sites as either Ni-TCS or Ni-INC species, with the CN equal to 6 for each Ni-Mn  
338 shell (**Figs. 4 and EA5**). For the high loading sample (Ni 0.18), we report the fitting parameters  
339 for the scenarios where a moderate proportion of Ni binds at particle edges either in DES or DCS  
340 geometries by setting the corresponding CN of the Ni-Mn shells equal to 4 or 5 (**Table 3**). The  
341 final fits included two additional shells (i.e., Ni-O<sub>3</sub> and Ni-Mn<sub>2</sub><sup>CS</sup>) to account for longer-distance  
342 Ni-O/Mn pair correlations corresponding to the TCS species (Peña et al., 2010). The fitted  
343 Debye-Waller factors of the first Ni-Mn<sup>CS</sup> shell were in the range  $0.007 - 0.010 \text{ \AA}^{-1}$ , which is  
344 comparable to the values previously reported for Ni-CS species on birnessite (Manceau et al.,  
345 2007; Peña et al., 2010; Zhu et al., 2010b). Based on the fitted values of  $f$  (**Table 3**), we conclude  
346 that CS complexes represent 80 – 87 % of the total adsorbed Ni at both surface loadings. Using  
347 the relationship  $q_{\text{Ni-CS}} = q * f$ , we estimate approximately 0.04 and 0.15 mol Ni mol<sup>-1</sup> Mn in the  
348 CS geometry for samples Ni 0.05 and Ni 0.18, respectively. The uncertainty in the fitted  
349 parameter,  $f$ , and thus Ni speciation, ranged from 2 to 4 %. However, we assign a 20 %  
350 uncertainty to these Ni speciation estimates to be consistent with typical uncertainties associated

351 with coordination numbers. Although the amount of the ES species is small (0.01 – 0.04 mol Ni  
352 mol<sup>-1</sup> Mn), the presence of a small but real fraction of Ni-Mn<sup>ES</sup> species is supported by  
353 significant improvement in the fit statistics upon addition of the Ni-Mn<sup>ES</sup> to the fit (R-factor  
354 decreased from 0.046 to 0.013).

### 355 3.2.2 Coordination environment of Ni sorbed by Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub>

356 Nickel K-edge EXAFS spectra and corresponding Fourier transforms for Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub>  
357 equilibrated with Ni are shown in **Fig. 5 and EA6**. The Fourier transforms have dominant peaks  
358 at 1.6, 2.5, and 3.1 Å ( $R + dR$ ) due to Ni-O, Ni-Mn, and Ni-Mn scattering, respectively. The Ni-  
359 Mn shells are at positions similar to those observed for the  $\delta$ -MnO<sub>2</sub> samples, but the first Ni-Mn  
360 peak appears shifted, from 2.4 Å to 2.5 Å ( $R + dR$ ). This peak is best-resolved for the sample  
361 with the lowest Ni loading, which shows the least peak overlap between the two Ni-Mn shells.  
362 Finally, in contrast to the Fourier-transformed EXAFS spectra for the  $\delta$ -MnO<sub>2</sub> samples, the  
363 Fourier-transformed EXAFS spectra for Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub> show no structure for  $R + dR > 4$  Å.

364 Fits to the EXAFS spectra from the Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub> samples resulted in interatomic  
365 distances of  $2.04 \pm 0.01$  Å,  $3.05 \pm 0.03$  Å and  $3.47 \pm 0.02$  Å for the Ni-O, Ni-Mn<sup>ES</sup> and Ni-Mn<sup>CS</sup>,  
366 respectively (**Table 4**). The Ni-Mn<sup>CS</sup> distance is identical to that obtained for Ni sorbed on  $\delta$ -  
367 MnO<sub>2</sub>. However, the Ni-Mn<sup>ES</sup> distance is longer by 0.18 Å than the Ni-Mn<sup>ES</sup> distance for  $\delta$ -  
368 MnO<sub>2</sub>, but it is similar to the Ni-Mn distance reported for the Ni complexes at the edge sites in  
369 triclinic birnessite (Peacock and Sherman, 2007; Zhu et al., 2010b). Indeed, the Fourier-  
370 transformed EXAFS spectrum for our TcBi sample showed a major second-shell peak at 2.5 Å  
371 ( $R + dR$ ), which was fit well with  $3.2 \pm 0.45$  Mn atoms at  $3.09 \pm 0.01$  Å (**Table 4, Figs. 5 and**

372 **EA7**). Thus, the observed elongation of the Ni-Mn<sup>ES</sup> distance in Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub> is consistent with  
373 coordination of Ni to Mn(III) octahedra in the ES configuration.

374 In the shell-by-shell fits, the scenario where CS species form exclusively at the vacancy  
375 sites [ $CN(\text{Ni-Mn}^{\text{CS}})=6$ ] resulted in an unreasonably high Debye-Waller factor ( $>0.025 \text{ \AA}^2$ ) and  
376 thus was excluded. The absence of a significant fraction of Ni-TCS species is also supported by  
377 the amplitudes of the Ni-Mn<sup>CS</sup> shell, as well as the higher-order shells, which are significantly  
378 attenuated relative to those of the  $\delta$ -MnO<sub>2</sub> samples. Moreover, since Mn<sup>III</sup>- $\delta$ -MnO<sub>2</sub> has both  
379 Mn(III) and Mn(IV) atoms, the  $\sigma^2$  values of the ES species were expected to exhibit higher  
380 values than in  $\delta$ -MnO<sub>2</sub> due to higher disorder in interatomic distances and thus  $\sigma^2$  values of  
381  $0.014 \text{ \AA}^{-1}$  (twice as large in  $\delta$ -MnO<sub>2</sub>) or lower were considered as reasonable. In samples Ni 0.01  
382 and Ni 0.04, shell-by-shell fits with  $CN(\text{Ni-Mn}^{\text{ES}})$  and  $CN(\text{Ni-Mn}^{\text{CS}})$  set equal to 2 - 3 and 3 - 4,  
383 respectively, returned statistically-similar results. In **Table 4** and **Figs. 5** and **EA6** we report the  
384 fits obtained with  $CN(\text{Ni-Mn}^{\text{ES}}) = 2$  and  $CN(\text{Ni-Mn}^{\text{CS}}) = 4$ . The  $\sigma^2$  values were  $0.009 - 0.012 \text{ \AA}^{-1}$   
385 for the Ni-Mn<sup>ES</sup> shell and  $0.006 - 0.007 \text{ \AA}^{-1}$  for the Ni-Mn<sup>CS</sup> shell, which are consistent with the  
386 values reported for Ni-MnO<sub>2</sub> surface complexes (Manceau et al., 2007; Peña et al., 2010; Zhu et  
387 al., 2010b). The fits indicate a mixture of Ni-ES and Ni-CS complexes at all surface loadings  
388 studied: 39 - 61 % Ni-ES ( $q_{\text{Ni-ES}} = 0.005 - 0.049 \text{ mol Ni mol}^{-1} \text{ Mn}$ ) and 61 - 39 % Ni-CS ( $q_{\text{Ni-CS}}$   
389  $= 0.005 - 0.031 \text{ mol Ni mol}^{-1} \text{ Mn}$ , with an uncertainty of 20 - 29 % as determined from the  
390 uncertainty in  $f$ .

### 391 **3.3. Geometry optimizations of Ni edge surface species**

392 Geometry-optimized structures of Ni edge surface species are summarized in **Fig. 2** and  
393 **Table 5**. Overall, the average Ni-O distance [ $d(\text{Ni-O})$ ] ranges from  $2.08 - 2.11 \text{ \AA}$  for all model

394 surface complexes. Our geometry optimizations also show significant overlap in  $d(\text{Ni-Mn})$   
 395 obtained for surface complexes with similar connectivity between the Ni and Mn octahedra  
 396 (**Table 5**). For example, the value of  $d(\text{Ni-Mn})$  for Ni-DCS (**Table 5**) is within 0.02 Å of  $d(\text{Ni-}$   
 397  $\text{Mn})$  for Ni-TCS (**Table 3**). Thus, Ni-DCS cannot be distinguished experimentally from Ni-TCS  
 398 based solely on the Ni-Mn interatomic distance. In addition, the protonation of the doubly  
 399 coordinated oxygen atom ( $\text{O}_{2\text{Mn}}$ ) does not affect  $d(\text{Ni-Mn})$ , as indicated by  $d(\text{Ni-Mn}) = 3.45$  Å  
 400 obtained for both the deprotonated ( $\text{DCS}_0$ ) and protonated ( $\text{DCS}_\text{H}$ ) DCS structures. Finally, the  
 401 Ni-Mn distance (2.89 Å) obtained for the Ni-DES complex, where Ni binds to two Mn(IV)  
 402 octahedra via two doubly-coordinated O ( $\text{DES}_{\text{O}2\text{Mn}}$ ), is similar to the Ni-Mn distance (2.91 Å) for  
 403 ES, where Ni binds to three Mn(IV) octahedra, and to the Ni-Mn distance (2.87 Å) reported for  
 404 Ni-INC, where Ni binds to six Mn(IV) octahedra (Peacock, 2009; Peacock and Sherman, 2007;  
 405 Peña et al., 2010). Therefore, the INC,  $\text{DES}_{\text{O}2\text{Mn}}$  and ES species also cannot be resolved using  
 406 only  $d(\text{Ni-Mn})$  (**Fig. 2**).

407 In geometry optimizations of the nanodisk with Mn(III) octahedra located at the edges,  
 408 we found that  $d(\text{Ni-Mn})$  in Ni-DES is sensitive to the valence of the Mn to which Ni is connected  
 409 by O. In the absence of Mn(III), when Ni is coordinated to two singly-coordinated O and one  
 410 doubly-coordinated O, forming  $\text{DES}_{\text{O}2\text{Mn}}$ ,  $d(\text{Ni-Mn})$  is 2.89 Å. When one of the Mn(IV)  
 411 octahedra was replaced with a Mn(III) octahedron ( $\text{DES}_{\text{O}2\text{Mn}}^{1\text{Mn(III)}}$ ),  $d(\text{Ni-Mn})$  increased slightly,  
 412 from 2.89 Å to 2.91 Å. In geometry-optimized  $\text{DES}_{\text{O}3\text{Mn}}$  (**Fig. 2**), Ni coordinates to one triply-  
 413 coordinated O and two singly-coordinated O (i.e., the Ni octahedron “flips” onto the basal plane  
 414 at the particle edge). When one or two of the Mn(IV) octahedra to which Ni binds were replaced  
 415 with Mn(III) octahedra to form  $\text{DES}_{\text{O}3\text{Mn}}^{1\text{Mn(III)}}$  or  $\text{DES}_{\text{O}3\text{Mn}}^{2\text{Mn(III)}}$ , respectively,  $d(\text{Ni-Mn})$  increased from  
 416 2.97 Å to 3.05 Å (**Table 5**). This longer distance, caused by the presence of Mn(III) at the

417 particle edges in  $\text{DES}_{03\text{Mn}}^{2\text{Mn(III)}}$ , corresponds well to the experimentally observed Ni-Mn interatomic  
418 distance for Ni sorbed on TcBi [ $d(\text{Ni-Mn}) = 3.09 \text{ \AA}$ ] and, importantly, to the Ni-Mn interatomic  
419 distance observed for Ni sorbed on  $\text{Mn}^{\text{III}}\text{-}\delta\text{-MnO}_2$  [ $d(\text{Ni-Mn}) = 3.01 - 3.05 \text{ \AA}$ ].

## 420 **4. DISCUSSION**

421 In previous studies, attempts to resolve the role of particle edges in trace metal sorption  
422 by birnessite minerals have been limited by i) co-variation in the specific surface area and  
423 Mn(III) content of the minerals investigated and ii) a lack of sufficient molecular-scale  
424 information to determine the structural parameters of surface complexes formed. In the current  
425 study, the hexagonal birnessite minerals used were characterized by large specific surface areas  
426 and differing Mn(III) contents. The large specific surface areas provide ample edge surface area  
427 for metal sorption, whereas the large differences in Mn(III) content allowed determination of the  
428 influence of Mn(III) on Ni sorption mechanisms without confounding effects from varying  
429 specific surface area.

### 430 **4.1. Ni sorption at particle edges of $\delta\text{-MnO}_2$**

431 Nickel K-edge EXAFS spectroscopy showed that the particle edges of  $\delta\text{-MnO}_2$  at pH 6.6  
432 become reactive at surface loadings exceeding the vacancy content. At a loading of  $0.18 \text{ mol Ni}$   
433  $\text{mol}^{-1} \text{ Mn}$ , the sorption of Ni at edge surfaces was suggested by the decreased amplitude of the  
434 Ni-Mn<sup>CS</sup> shell in the Fourier-transformed EXAFS spectra (**Fig. 4**). Our geometry optimizations  
435 showed that the Ni-Mn distance in both Ni-TCS and Ni-DCS structures were for all practical  
436 purposes identical. This result is consistent with previous reports for Ni surface complexes  
437 (Manceau et al., 2007) and similar surface complexes of Pb on  $\text{MnO}_2$  (Kwon et al., 2010). For

438 the fitting scenario with  $CN(\text{Ni-Mn}^{\text{CS}}) = 5$  and  $CN(\text{Ni-Mn}^{\text{ES}}) = 6$  (**Table 3, Figs. 4 and EA5**), the  
439 fractions of the ES and CS complexes were 13 % (or  $0.02 \text{ mol Ni}^{\text{ES}} \text{ mol}^{-1} \text{ Mn}$ ) and 87 % (or  $0.16$   
440  $\text{mol Ni}^{\text{CS}} \text{ mol}^{-1} \text{ Mn}$ ), respectively. Assuming that  $CN(\text{Ni-Mn}^{\text{TCS}}) = 6$  and  $CN(\text{Ni-Mn}^{\text{DCS}}) = 2$   
441 (**Fig. 1**), we estimate that the DCS complex constitutes 22 % of the adsorbed Ni or  $0.04 \text{ mol Ni}$   
442  $\text{mol}^{-1} \text{ Mn}$ . The similarity in fitting statistics when the coordination number of the  $\text{Ni-Mn}^{\text{ES}}$  shell  
443 was varied from 3 to 6 (**Table EA1**) suggests that  $\text{Ni-DES}_{\text{O}_2\text{Mn}}$  or  $\text{Ni-ES}_{\text{O}_2\text{Mn}}$  complexes may  
444 form at particle edges, contributing at most  $0.02 \text{ mol Ni mol}^{-1} \text{ Mn}$  (or 10 %). Thus, in the high  
445 loading sample 80 – 90 % of the adsorbed Ni, or  $0.14 \pm 0.04 \text{ mol Ni mol}^{-1} \text{ Mn}$ , is sorbed at the  
446 vacancies (TCS/INC), while the contribution from edge species is at most 10 – 20 %, or  $0.02 -$   
447  $0.04 \text{ mol Ni mol}^{-1} \text{ Mn}$  as DES/ES/DCS. The predominance of Ni surface complexes at the  
448 vacancy sites at low loadings and increase in Ni-DCS and Ni-DES species at high loadings is  
449 consistent with the high sorption affinity and capacity of  $\delta\text{-MnO}_2$  for Ni (**Fig. 3**).

#### 450 **4.2. Ni sorption at particle edges of $\text{Mn}^{\text{III}}\text{-}\delta\text{-MnO}_2$**

451 For  $\text{Mn}^{\text{III}}\text{-}\delta\text{-MnO}_2$ , shell-by-shell fits showed a mixture of 39 – 61 % Ni-ES and 61 – 39  
452 % Ni-CS complexes. The best fits were obtained for  $CN(\text{Ni-Mn}^{\text{ES}})$  equal to 2 - 3 and  $CN(\text{Ni-}$   
453  $\text{Mn}^{\text{CS}})$  equal to 3 – 4, which suggest a 75 - 100 % contribution of the DES species to the Ni-  
454  $\text{Mn}^{\text{ES}}$  shell and a 50 - 75 % contribution of the DCS species to the  $\text{Ni-Mn}^{\text{CS}}$  shell. Thus, the  
455 analysis of Ni K-edge EXAFS spectra suggested 29 – 61 % Ni-DES and 46 – 20 % of Ni-DCS  
456 complexes in samples with loadings of  $0.01 - 0.08 \text{ mol Ni mol}^{-1} \text{ Mn}$ , which sums to around 80 %  
457 Ni adsorbed at edge surface sites. We estimate that the highest loading sample (Ni 0.08)  
458 contained about  $0.06 \pm 0.02 \text{ mol Ni mol}^{-1} \text{ Mn}$  adsorbed at particle edges. Although the  
459 uncertainty in these estimates is relatively large (20 - 29 %), the majority of Ni is sorbed at the  
460 particle edges in  $\text{Mn}^{\text{III}}\text{-}\delta\text{-MnO}_2$  at pH 6.6. The large fraction of Ni edge species in  $\text{Mn}^{\text{III}}\text{-}\delta\text{-MnO}_2$

461 as compared to  $\delta$ -MnO<sub>2</sub> can be explained by the blocking effect of interlayer Mn(II,III)  
462 occupying the high-affinity vacancy sites (see **Electronic Annex**). This inference is confirmed  
463 by the sorption isotherm for Ni on Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub>, which, unlike the H-curve isotherm observed  
464 for  $\delta$ -MnO<sub>2</sub>, does not display high affinity and sorption capacity (**Fig. 3**). The proposed blocking  
465 mechanism also explains the decrease in metal sorption capacity observed with increasing  
466 Mn(II,III) content in previous studies of birnessites (Lafferty et al., 2010; Wang et al., 2012;  
467 Zhao et al., 2009).

468 Trivalent Mn at the particle edges of Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub> also changes the coordination  
469 geometry of Ni surface complexes at the edge sites. Structural modeling of the Ni K-edge  
470 EXAFS spectra showed that Mn(III) shifted the Ni-Mn<sup>ES</sup> distance from 2.84 Å in  $\delta$ -MnO<sub>2</sub> to 3.01  
471 – 3.05 Å in Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub>, close to the Ni-Mn distance obtained for TcBi (**Tables 3 and 4**).  
472 Thus, we propose that, in Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub>, Ni forms Ni-DES surface complexes wherein the Ni-  
473 Mn distance is elongated due to Mn(III) located at the particle edges.

474 Previously, the elongated Ni-Mn distance in TcBi has been also assigned to Ni complexes  
475 formed at the edge surface sites on TcBi (Peacock and Sherman, 2007; Zhu et al., 2010b).  
476 However, TcBi is a microcrystalline Mn(III)-containing birnessite with a specific surface area of  
477 only 30 m<sup>2</sup>/g and relatively large particles. For 50 nm square particles, less than 2 % of the total  
478 number of Mn octahedra would be located at the particle edges. In addition, the ordering of  
479 Mn(III) into Mn(III)-rich rows in TcBi (Drits et al., 1997; Lanson et al., 2002a; Silvester et al.,  
480 1997) creates undersaturated triply-coordinated oxygen atoms on the basal plane, thus making  
481 the triangular cavity between these oxygen atoms reactive toward metal cation sorption. Rather  
482 than forming a DES complex at particle edges, Ni may be adsorbed as a triple-edge sharing  
483 (TES) complex on these triangular cavities in the basal plane. This conclusion is consistent with

484 our EXAFS-derived structural parameters, which showed that Ni-ES in TcBi has three Mn  
485 neighbors, two of which should be Mn(III). In Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub>, however, the occurrence of the  
486 TES complex is unlikely because it would require significant ordering of the Mn(III) in the  
487 MnO<sub>2</sub> sheet; such ordering of Mn(III) is not consistent with our Mn K-edge EXAFS spectra.  
488 High specific surface area (ca. 200 m<sup>2</sup> g<sup>-1</sup>) also favors DES over TES complexes in Mn<sup>III</sup><sub>δ</sub>-  
489 MnO<sub>2</sub>.

490 The coordination of Ni to Mn(III) at particle edges of Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub> is further supported  
491 by our geometry optimizations, which showed that Mn(III) influenced both the Ni-Mn distance  
492 and bonding geometry of the Ni-DES species. In the absence of Mn(III), Ni was coordinated at  
493 the edge sites in the DES<sub>O<sub>2</sub>Mn</sub> configuration, while the replacement of Mn(IV) with Mn(III)  
494 favored the formation of the DES<sub>O<sub>3</sub>Mn</sub><sup>2Mn(III)</sup> species (**Fig. 2**). The DES<sub>O<sub>3</sub>Mn</sub><sup>2Mn(III)</sup> coordination geometry  
495 is characterized by a Ni-Mn distance of 3.05 Å, which matches the Ni-Mn distance of 3.01 –  
496 3.05 Å detected by EXAFS spectroscopy. In this coordination geometry, Ni binds to a triply-  
497 coordinated oxygen O<sub>3Mn</sub> and “flips” onto the basal plane at particle edges. The formation of the  
498 “flipped” DES complex can be rationalized by bond-valence analysis. When a triply-coordinated  
499 O is bonded to three Mn(IV) (i.e., O<sub>3Mn</sub> in DES<sub>O<sub>2</sub>Mn</sub>), each Mn(IV) brings +4/6 valence units  
500 (v.u.) to O<sub>3Mn</sub> (i.e., 3 × 4/6 = 2), rendering this O<sub>3Mn</sub> saturated. The substitution of Mn(IV) by  
501 Mn(III) (as in DES<sub>O<sub>3</sub>Mn</sub><sup>2Mn(III)</sup>) makes the O<sub>3Mn</sub> undersaturated (i.e., 4/6 + 2 × 3/6 = 10/6 < 2 ) and  
502 thus reactive towards metal cation sorption. Consequently, when Mn(III) is present at particle  
503 edges, Ni may preferentially form a DES<sub>O<sub>3</sub>Mn</sub><sup>2Mn(III)</sup> complex in which O<sub>3Mn</sub> becomes saturated (10/6  
504 + 2/6 = 2). In addition, the Ni DES<sub>O<sub>3</sub>Mn</sub> geometry may result in a more stable complex at the  
505 oxide surface than one with the DCS geometry because DES<sub>O<sub>3</sub>Mn</sub> binds with one O<sub>3Mn</sub> and two  
506 O<sub>2Mn</sub>, while DCS binds with only two O<sub>2Mn</sub> (**Fig. 2**).

## 507 5. CONCLUSIONS

508 In this study we demonstrate that the edge surfaces of hexagonal birnessite nanoparticles  
509 are reactive towards trace metal sorption at circumneutral pH values (6.6). In unmodified and  
510 modified  $\delta$ -MnO<sub>2</sub>, Ni sorbed at particle edges under conditions where the vacancy sites were  
511 unavailable for sorption. For  $\delta$ -MnO<sub>2</sub>, the fraction of Ni on edge sites was 10 to 20 % and  
512 represented a low loading (0.02 – 0.04 mol Ni mol<sup>-1</sup> Mn) relative to the loading of Ni on vacancy  
513 sites (ca. 0.14 mol Ni mol<sup>-1</sup> Mn) and total surface excess (0.18 mol Ni mol<sup>-1</sup> Mn). For Mn<sup>III</sup><sub>δ</sub>-  
514 MnO<sub>2</sub>, sorption at particle edges was significant, accounting for around 80 % of the total sorbed  
515 Ni. Moreover, because Mn(II,III) was present initially in the sorbent, Ni partitioned to the  
516 particle edges at all surface loadings studied (0.01 – 0.08 mol Ni mol<sup>-1</sup> Mn).

517 Based on EXAFS spectroscopy and DFT geometry optimizations, we conclude that the  
518 DCS geometry is favored over the DES geometry in  $\delta$ -MnO<sub>2</sub>, whereas DCS and DES complexes  
519 are comparably important in Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub>. The presence of Mn(III) at particle edges in  
520 Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub> forced Ni into the DES<sub>O<sub>3</sub>Mn</sub><sup>2Mn(III)</sup> geometry, thereby stabilizing the DES complex by  
521 providing better charge balance and increasing the number of surface oxygens binding Ni from  
522 two to three. This Ni-DES species has not been identified in previous studies with  $\delta$ -MnO<sub>2</sub> or  
523 acid birnessite (Peacock and Sherman, 2007; Yin et al., 2012), a result which may be attributed  
524 to differences in mineral specific surface area or Mn(III) content and distribution. Similar  
525 structural parameters to those we identified for Ni-DES have been reported for Fe sorbed on  $\delta$ -  
526 MnO<sub>2</sub>, although the Mn(III) content of the sorbent after reaction with Fe(III)-desferrioxamine B  
527 was not reported (Duckworth et al., 2008)

528           The results presented herein and in previous studies (Manceau et al., 2007; Yin et al.,  
529 2012) confirm that EXAFS spectroscopy is limited in its ability to distinguish between surface  
530 complexes on basal surfaces and edge surfaces because interatomic distances are similar for  
531 complexes with similar polyhedral connectivity (e.g., Ni-TCS and Ni-DCS), as shown by our  
532 DFT geometry optimizations. In addition, coordination numbers are poorly constrained in the  
533 structural analysis of EXAFS spectra (Ravel and Kelly, 2007). Only by combining DFT  
534 geometry optimizations and spectroscopic titrations were we able to identify the structural  
535 parameters and coordination geometries of Ni edge complexes. In addition, while we expect Ni  
536 and other trace metals to behave similarly, the detection of Fe, Co, Cu, Zn or Pb surface  
537 complexes at the edges of birnessite would be more difficult due to the varied coordination these  
538 metals display. For instance, Zn forms complexes with both tetrahedral and octahedral  
539 geometries on MnO<sub>2</sub> (Fuller and Bargar, 2014; Grangeon et al., 2012; Toner et al., 2006), Co  
540 shows the +2 and +3 valence states (Manceau et al., 1997), and Cu and Pb deviate from  
541 symmetric octahedral coordination (Kwon et al., 2010; Manceau et al., 2002; Takahashi et al.,  
542 2007; Villalobos et al., 2005).

543           In summary, the propensity for trace metals to adsorb at particle edges depends on the i)  
544 density of edge sorption sites, ii) valence of Mn atoms at the particle edges, which can modify  
545 the type of surface complex formed, and iii) abundance of vacancy sites, which are high-affinity  
546 sorption sites but can be blocked by Mn(II,III). The blocking effect of Mn(II, III) also leads to a  
547 significant reduction in the overall sorption capacity of Mn oxides. Although the density of  
548 reactive edge surface sites, vacancy content and sorbed Mn(II,III) is pH dependent (Manceau et  
549 al., 2013; Zhu et al., 2010a), thus influencing the overall reactivity of the edge sites, our findings  
550 are relevant for a range of natural settings with circumneutral pH. Natural birnessites occur as

551 nanoparticles characterized by high surface area and varying amounts of Mn(III), which may  
552 originate from the incomplete oxidation of Mn(II) to Mn(IV) or from the reduction of Mn(IV) by  
553 redox-active metals (e.g., Co(II), Cr(III), As(III), U(IV)), reducing moieties in natural organic  
554 matter, organic contaminants or microorganisms. Thus, understanding how Mn(III) influences  
555 the partitioning of metals to different binding sites on birnessite furthers our ability to predict the  
556 controls that Mn oxides exert on the distribution and bioavailability of trace metals in the  
557 environment.

**Table 1****Table 1.** Physicochemical properties of Mn oxide samples

Sample ID	Specific surface area <sup>a</sup> (m <sup>2</sup> /g)	AMON <sup>b</sup>	Na/Mn <sup>c</sup> (mol %)	Water content <sup>d</sup> (%)	Particle size in <i>ab</i> plane <sup>e</sup> (nm)
$\delta$ -MnO <sub>2</sub>	254 <sup>f</sup>	4.01 ± 0.05	22.7 ± 0.5	< 20	2 – 4
TcBi	30	3.84 ± 0.04	30.0 ± 0.5	8.9	25 – 50
$\delta$ -MnO <sub>2</sub> (pH 6.6; 48 h)	232	3.95 ± 0.05	6.5 ± 0.5	-	-
Mn <sup>III</sup> $\delta$ -MnO <sub>2</sub> (pH 6.6; 48 h)	200	3.65 ± 0.05	3.0 ± 0.5	-	-

<sup>a</sup> Determined by a 5-point BET N<sub>2</sub>(g) adsorption isotherm (Micromeritics Gemini 2375)

<sup>b</sup> **Section 2.3**

<sup>c</sup> Measured by ICP-OES after complete dissolution in 1.5 % HNO<sub>3</sub> and 10 mM oxalic acid

<sup>d</sup> Determined by thermogravimetric analysis (Mettler Toledo TG/SDTA 851e)

<sup>e</sup> Determined from transmission electron microscopy (TEM) images

<sup>f</sup> Duckworth and Sposito (2007)

**Table 2**

**Table 2.** Samples investigated by EXAFS spectroscopy. Surface loading ( $q$ ) and concentration of Mn(II) measured in solution ( $c_{\text{Mn}}$ ) are reported for each sample; separate samples were used for AMON determination.

Mineral	Sample ID <sup>a</sup>	EXAFS		AMON		
		$q$ (mol Ni mol <sup>-1</sup> Mn)	$c_{\text{Mn}}$ ( $\mu\text{M}$ )	$q$ (mol Ni mol <sup>-1</sup> Mn)	$c_{\text{Mn}}$ ( $\mu\text{M}$ )	AMON
$\delta$ -MnO <sub>2</sub>	$\delta$ -MnO <sub>2</sub>	-	n.d. <sup>b</sup>	-	n.d.	3.95
	Ni 0.05	0.05	n.d.	0.05	n.d.	3.95
	Ni 0.18	0.18	n.d.	0.18	n.d.	4.01
Mn <sup>III</sup> <sub>δ</sub> -MnO <sub>2</sub>	Mn <sup>III</sup> <sub>δ</sub> -MnO <sub>2</sub>	-	71.7	-	74.2	3.65
	Ni 0.01	0.01	63.1	0.01	76.8	3.68
	Ni 0.02	0.02	82.1	0.03	87.8	3.70
	Ni 0.04	0.04	120.9	0.06	123.7	3.74
	Ni 0.08	0.08	178.1	0.09	174.8	3.73
TcBi	Ni 0.02	0.02	n.d.	0.02	n.d.	-

<sup>a</sup>The sample ID contains the sorbent name or surface loading in units of mol Ni mol<sup>-1</sup> Mn.

<sup>b</sup>Not detected

**Table 3**

**Table 3.** Summary of EXAFS fitting parameters obtained for  $\delta$ -MnO<sub>2</sub> samples. Loadings corresponding to CS and ES bonding environments are calculated according to  $q_{\text{Ni-CS}} = q * f$  and  $q_{\text{Ni-ES}} = q * (1 - f)$ , respectively.

Sample	Shell ID <sup>a</sup>	A <sup>b</sup>	R (Å)	$\sigma^2$ (Å <sup>2</sup> )	$\Delta E_0$ (eV)	Red chi <sup>2</sup>	R- factor	f	$q_{\text{Ni-ES}}/$ $q_{\text{Ni-CS}}$

Nind/Nvar		26/12							

<sup>a</sup> Ni-O and Ni-Mn shell labels follow from Peña et al. (2010); in the text Ni-Mn<sub>1</sub> is referred to as Ni-Mn.

<sup>b</sup> The amplitude (A) of Ni-O and Ni-Mn shells are defined as the product of the CN and a scaling parameter (f), where f refers to the fraction of Ni in the CS geometry and (1 - f) refers to the fraction of Ni in the ES geometry.

<sup>c</sup> the uncertainty in the surface excess q is estimated assuming a 20 % uncertainty in the fraction f.

**Table 4**

**Table 4.** EXAFS fitting parameters obtained for TcBi and Mn<sup>III</sup><sub>δ</sub>-MnO<sub>2</sub> samples. Loadings corresponding to CS and ES bonding environments are calculated according to  $q_{CS} = q * f$  and  $q_{ES} = q * (1 - f)$ , respectively.

Sample	Shell ID <sup>a</sup>	$A^b$	$R$ (Å)	$\sigma^2$ (Å <sup>2</sup> )	$\Delta E_0$ (eV)	Red chi <sup>2</sup>	R- factor	$f$	$q_{Ni^{ES}}/$ $q_{Ni^{CS}}$

## Figure captions

1 **Fig. 1.** Schematic representations of Ni-birnessite surface complexes: Ni = black, Mn octahedra =  
2 hatched, O = grey. The ideal coordination number (*CN*) and interatomic distance between Ni and  
3 Mn [ $R(\text{Ni-Mn})$ ] for each surface complex geometry is included below each cartoon, where TCS  
4 **(a)** refers to a triple-corner-sharing complex wherein a metal cation binds to the three doubly-  
5 coordinated oxygen atoms surrounding a vacancy site; INC **(b)** refers to the incorporation of a  
6 metal cation into a vacancy in the  $\text{MnO}_2$  sheet; DCS **(c)** refers to a double-corner-sharing complex  
7 where a metal cation binds to two singly-coordinated oxygen atoms at the particle edges; DES **(d)**  
8 refers to a double-edge-sharing complex wherein a metal cation binds to two singly- and one  
9 doubly-coordinated oxygen atoms at the particle edges.

10

11 **Fig. 2.** Structures of geometry-optimized Ni surface complexes. Color scheme: blue = Ni; grey =  
12 Mn; red = O; pink = H. In  $\text{DES}_{\text{O}_2\text{Mn}}$ , Ni binds with  $\text{O}_{2\text{Mn}}$  and two  $\text{O}_{1\text{Mn}}$ . In  $\text{DES}_{\text{O}_3\text{Mn}}$ , Ni binds with  
13  $\text{O}_{3\text{Mn}}$  and two  $\text{O}_{1\text{Mn}}$ . The  $\text{DES}_{\text{O}_3\text{Mn}}^{2\text{Mn(III)}}$  structure is like  $\text{DES}_{\text{O}_3\text{Mn}}$  with Ni bound to two Mn(III)  
14 octahedra. The ES structure has three Mn atoms, while DES has two Mn atoms in the first Ni-Mn  
15 coordination shell. In  $\text{DCS}_0$ , the  $\text{O}_{2\text{Mn}}$  is deprotonated, while in  $\text{DCS}_\text{H}$  it is protonated.

16

17 **Fig. 3.** Sorption isotherms of Ni on  $\delta\text{-MnO}_2$  (triangles) and  $\text{Mn}^{\text{III}}\text{-}\delta\text{-MnO}_2$  (circles) measured at  
18 pH 6.6. The lines are intended to guide the eye. Samples investigated by EXAFS spectroscopy are  
19 indicated by filled symbols.
